Preface to the Second Edition

Computational neuroscience offers multi-scale models that span complexity from the gene to the whole living system levels, and can span different time and spatial scales. Such models offer hypotheses for testing in biological systems. Computational neuroscience also offers advanced statistical and data analysis techniques and approaches to interpret and analyze complex data. Collaborative effort among several disciplines and a convergence of diversity of approaches to knowledge inquiry and seeking of solutions are hallmarks of the field. Data sharing and model sharing based on modern markup language syntax and semantics shore up this effort.

In the 7 years since the print publication of the first edition of Springer's *Encyclopedia for Computational Neuroscience* in 2015, computational neuroscience has advanced significantly. In keeping with the rapid advancement of the field, as a live document, the online encyclopedia is continuously undergoing change, and over 120,000 downloads have occurred. This second print edition offers 46 new entries covering growing areas such as modeling of disease states, neural-glial interactions, and advances in applying information theory to computational neuroscience.

Several international conferences in this field of study, such as the annual meeting of the Organization of Computational Neuroscience <http://www.cnsorg.org/> and COSYNE <http://cosyne.org>, continue to bring the global community together, and standard-setting organizations, such as the International Neuroinformatics Coordinating Facility <http://incf.org/>, assure open and fair data exchange.

The growing allocation of research funding for computational neuroscience reflects the importance for understanding complex neurobiological systems in health and disease and translating that knowledge for clinical applications as well as design and development of neurobiology-inspired engineered systems. In the USA, the National Science Foundation, the National Institutes of Health, and the Department of Energy support collaborative research in computational neuroscience. Bilateral funding commitments to these agencies have been made by national research grant supporting agencies in France, Germany, Israel, Japan, and Spain. Support for multilateral projects and collaborations is also available. Thus, a global community of computational neuroscientists engage in “collaboratories.”

The encyclopedia highlights achievements and approaches to describe basic neural function and major brain systems as well as biomedical applications in 579 entries and 42 overviews over distinct research areas in

computational neuroscience. In-depth articles, written by subject-matter experts from around the globe, provide comprehensive coverage of important topics, whereas short articles summarize individual concepts and key terms. The interplay between computational and theoretical approaches and experimental data is highlighted at all levels from molecular to cognitive. Available shared database resources are also covered. While overall alphabetically sorted, an introduction of each section of topics covered is presented in entries denoted “Overview,” which also provide organized links to section entries.

The level of description in the encyclopedia is aimed to make the material accessible to graduate students in the many disciplines that contribute to computational neuroscience while also providing a valuable reference to advanced researchers. Cited website links allow the access to a more detailed level of information when needed. For those with institutional access to the online SpringerReference enterprise, a hot-linked version of this encyclopedia is available under [springerlink.com](https://www.springerlink.com).

The editors in chief are pleased to present this second edition of the *Encyclopedia of Computational Neuroscience* and are looking forward to readers’ comments that will be taken to further improve and complete future updates of this work.

Dieter Jaeger
Ranu Jung

About the Editors

Dr. Dieter Jaeger is a professor in the Department of Biology at Emory University in Atlanta, Georgia. His research examines how basal ganglia impact decision-making and motor control in thalamo-cortical networks through modeling and systems physiological approaches.

Dr. Ranu Jung is Distinguished Professor of Biomedical Engineering and inaugural executive director of the Institute for Integrative and Innovative Research at the University of Arkansas, Fayetteville, Arkansas, where her research concerns neural engineering and computational neuroscience.

About the Section Editors

Vertebrate Pattern Generation

Jessica Ausborn Drexel University College of Medicine, Philadelphia, USA

Bayesian Approaches in Computational Neuroscience

Ulrik R. Beierholm Durham University, Durham, UK

Somatosensory System

Sliman J. Bensmaïa University of Chicago, Chicago, USA

Biochemical Signaling Pathways and Diffusion

Kim T. Blackwell George Mason University, Fairfax, USA

Neural Population Models and Cortical Field Theory

Ingo Bojak University of Reading, Reading, UK

Dynamical Systems

Alla Borisyuk University of Utah, Salt Lake City, USA

Spectral Methods in Neural Data Analysis

Steven L. Bressler Florida Atlantic University, Boca Raton, USA

Phase Response Curves

Carmen C. Canavier LSU Health Sciences Center, New Orleans, USA

Olfaction

Francesco Cavarretta Emory University, Atlanta, USA

Low Frequency Oscillations (Anesthesia and Sleep)

Diego Contreras University of Pennsylvania, Philadelphia, USA

Databases in Computational Neuroscience, Model Reproducibility

Sharon Crook Arizona State University, Tempe, USA

Auditory Sensing Systems

Rodica Curtu University of Iowa, Iowa City, USA

Multistability in Neurodynamics

Gennady Cymbalyuk Georgia State University, Atlanta, USA

LFP Analysis

Alain Destexhe Paris Saclay University, CNRS, Neuro-PSI, Gif sur Yvette, France

Information Theory

Alexander Dimitrov Washington State University, Vancouver, USA

Invertebrate Sensory Systems

Fabrizio Gabbiani Baylor College of Medicine, Houston, USA

Modeling Software Tools

Padraig Gleeson University College London, London, UK

Spike Train Analysis

Sonja Grün Jülich Research Centre, Jülich, Germany

Cable Theory

William R. Holmes Ohio University, Athens, USA

Neuromodulation

Leon D. Iasemidis Louisiana Tech University, Ruston, USA

Brain Scale Networks, Cortex, Synaptic Dynamics

Dieter Jaeger Emory University, Atlanta, USA

Databases in Computational Neuroscience

Jeanette Koteleski Royal Institute of Technology, Stockholm, Sweden

Olfaction

Christiane Linster Cornell University, Ithaca, USA

Retinal/Visual Interfaces (Models, Theory, Techniques)

Nigel H. Lovell UNSW, Sydney, Australia

Modeling of Disease - Physical and Molecular Levels

William W. Lytton SUNY Downstate Medical Center, Brooklyn, USA

Computational Neuroanatomy

David Mayerich University of Houston, Houston, USA

Spinal Interfaces

Jacob G. McPherson Washington University School of Medicine, St. Louis, USA

Vestibular System

Americo Migliaccio Neuroscience Research Australia, Sydney, Australia

Olfaction

Michele Migliore Institute of Biophysics, Palermo, Italy

Decision Making

Paul Miller Brandeis University, Waltham, USA

Dynamics of Disease States

John Milton The Claremont Colleges, Claremont, USA

Invertebrate Pattern Generation

Farzan Nadim New Jersey Institute of Technology/Rutgers University, Newark, USA

Modeling of Disease - Physical and Molecular Levels

Adam J. H. Newton Yale Center for Medical Informatics, New Haven, USA

Brain Machine Interface

Karim G. Oweiss University of Florida, Gainesville, USA

Neuronal Model Optimization

Astrid A. Prinz Emory University, Atlanta, USA

Brain Imaging

Jorge Riera Florida International University, Miami, USA

Basal Ganglia

Jonathan E. Rubin University of Pittsburgh, Pittsburgh, USA

Vertebrate Pattern Generation

Ilya A. Rybak Drexel University College of Medicine, Philadelphia, USA

Neuromorphic Engineering

Sylvain Saïghi University of Bordeaux, Bordeaux, France

Cerebellum

Fidel Santamaria The University of Texas at San Antonio, San Antonio, USA

Visual System

Thomas Serre Brown University, Providence, USA

Gamma and Theta Oscillations, Hippocampus

Frances K. Skinner Krembil Research Institute, University Health Network, Toronto, Canada

Astrocyte Models

Rahul Srinivasan Texas A&M Health Science Center, Bryan, USA

Compartmental Modeling, Ion Channel Types and Modeling

Volker Steuber University of Hertfordshire, Hatfield, UK

Deep Brain Stimulation (Models, Theory, Techniques)

Peter Alexander Tass Stanford University, Stanford, USA

Learning Rules

Joaquín J. Torres Universidad de Granada, Granada, Spain

Spinal and Neuromechanical Integration

Matthew Tresch Northwestern University, Evanston, USA

Astrocyte Models, Motoneurons and Neuromuscular Systems

Sharmila Venugopal University of California, Los Angeles, CA, USA

Peripheral Nerve Interfaces

Douglas J. Weber Department of Mechanical Engineering and the Neuroscience Institute, Carnegie Mellon University, Pittsburgh, PA, USA

Contributors

James J. Abbas School of Biological and Health Systems Engineering, Arizona State University, Tempe, AZ, USA

Overview

Auditory Sensing Systems: Overview

Rodica Curtu^{1,2} and Susan Denham³

¹Department of Mathematics, University of Iowa, Iowa City, IA, USA

²Iowa Neuroscience Institute, University of Iowa, Iowa City, IA, USA

³Cognition Institute and School of Psychology, Plymouth University, Plymouth, Devon, UK

Detailed Description

This second edition of the Encyclopedia of Computational Neuroscience includes updates to the first edition's entries based on new findings in the field, and publishes several new reviews on recent topics of interest and modelling techniques for the study of auditory sensing systems. We thank the authors for their willingness to contribute to this section and thus provide a rich scientific resource on auditory neuroscience, for young and senior researchers alike.

Auditory sensing, or the sense of hearing, is concerned with detecting and extracting information from pressure waves in the surrounding medium, typically air or water. Since waves are generated by movements or collisions, this primarily tells the perceiver about things happening in the environment. In addition, since pressure

waves can be reflected, absorbed, and refracted by other objects, these pressure waves also contain a great deal of contextual information about the environment and the objects in it. A fundamental challenge for the auditory system is to segregate the contributions of individual sound sources to the sound pressure waves received by the sensors as these are made up of a combination of all concurrent sources and their various reflections. Sounds unfold in time, so modelers of auditory processing cannot ignore time and the need to process signals within time; this becomes especially challenging when considering the multiscale nature of the information contained within sounds.

Possibly due to the complexity of the problem, many aspects of auditory processing have not yet been modeled at a detailed neurocomputational level. In addition, a great deal of processing occurs even before the incoming signals reach cortex; with the result that there are more models related to subcortical processing, than to higher level, putatively cortical, functions. The articles commissioned for the auditory sensing systems section therefore span a range of topics from qualitatively different point of view, with a strong focus on the functionality of the auditory system. Together they provide an interesting and insightful view of current understanding of auditory processing, with a great deal of useful information for modelers regarding the neuroanatomy and

neurophysiology of the auditory system, methodological approaches to studying the auditory system, and functional requirements and perceptual constraints on auditory processing.

A well-illustrated overview of the anatomy and physiology of the auditory system, including the extensive but poorly understood efferent system is covered by ► [“Anatomy and Physiology of the Mammalian Auditory System.”](#) A detailed account of efferent control of the auditory sensor, the cochlea, is presented in the article on the ► [“Physiology and Function of Cochlear Efferents.”](#) It is in the cochlea that the biological system begins to analyze the pressure waves over multiple time scales and to do so within the time constraints of the ongoing multiscale information flow.

Another point of major transformation occurs at the gateway to the cortex, described in the article ► [“Auditory Thalamocortical Transformations.”](#) Three further overview articles dealing with electrophysiological correlates of auditory perception: ► [“Auditory Event-Related Potentials,”](#) ► [“Auditory Brainstem Responses,”](#) and ► [“Electrophysiological Indices of Speech Processing”](#) document methodological approaches to studying high-level perceptual functions. Specific aspects of the functional neurophysiology of the thalamocortical auditory system are addressed in a number of articles. The articles ► [“Associations and Rewards in the Auditory Cortex”](#) (revised) and ► [“Context-Dependent Processing in Auditory Cortex”](#) (revised) demonstrate that the auditory cortical code needs to be viewed in more complex terms than simple acoustic feature representations. For example, neural correlates of reward are found even within primary auditory cortex (► [“Associations and Rewards in the Auditory Cortex”](#)). In contrast, the articles ► [“Spectrotemporal Receptive Fields,”](#) ► [“Stimulus-Specific Information,”](#) and ► [“Stimulus Reconstruction from Cortical Responses”](#) show how auditory cortical activity can in some circumstances be usefully interpreted in terms of acoustic feature combinations.

An overview of theories and models of higher-level aspects of auditory perception are presented in ► [“Auditory Perceptual Organization,”](#)

► [“Music Processing in the Brain,”](#) ► [“Neural Coding of Speech Sounds,”](#) ► [“Pulse-Resonance Sounds,”](#) ► [“Auditory Memory”](#) (revised), ► [“Acoustic Timbre Recognition”](#) ► [“Pitch Perception, Models,”](#) ► [“Rhythm Perception: Pulse and Meter,”](#) and ► [“Sound Localization in Mammals and Models.”](#) These diverse topics emphasize the different ways in which sound is interpreted by the brain, while the article ► [“Tinnitus, Models”](#) shows how modelling may help advance understanding of a perceptual phenomenon that plagues 10–15% of the population.

The section also contains articles which present more detailed neurocomputational models and theories more closely related to the biology. These tend either to relate to very specific functions (► [“Sound Localization in Mammals and Models”](#) (revised), ► [“Stimulus-Specific Adaptation, Models,”](#) ► [“Auditory Precedence Effect,”](#) and ► [“Masking and Masking Release”](#) (revised)), or relate to processes at or near the sensor (► [“Auditory-Nerve Response, Afferent Signals”](#) (revised) and ► [“Cochlear Inner Hair Cell, Model”](#)).

Finally, new entries in the Auditory Sensing Systems section focus on neural features of sound perception such as neuronal phase-locking to the spectrotemporal components of the acoustic signal (► [“Auditory Frequency-Following Responses”](#)), enhancement of the cortical representation of auditory signals in the presence of noise at moderate signal-to-noise ratio (► [“Auditory Cortex: Separating Signal from Noise”](#)), and perceptual organization of environmental sounds (► [“Environmental Sound Perception: Effects of Aging and Hearing Loss”](#)). They also present recent advancements in mathematical and computational modeling of auditory processing in the auditory pathway and auditory perceptual representation. The articles review modeling of the interaural and internal time and level differences (► [“Internally Coupled Ears \(ICE\): Biophysical Consequences and Underlying Mechanisms”](#)), modeling of sound-evoked extracellular voltages in the auditory brainstem (► [“Extracellular Voltage Recordings in the Medial Superior Olive, Modeling of”](#)), as well computational and statistical methods

used to study auditory stream segregation (► “Computational Models of Auditory Stream Segregation”).

Basal Ganglia: Overview

Jonathan E. Rubin

Department of Mathematics, University of Pittsburgh, Pittsburgh, PA, USA

Definition

The basal ganglia are a collection of four subcortical nuclei, the striatum, substantia nigra, globus pallidus, and subthalamic nucleus. They are components of several apparently segregated circuits that can be classified according to function as motor, oculomotor, associative, and limbic. Certain neurons in the basal ganglia are major sources of the neurotransmitter dopamine, associated with reward, while others receive dopaminergic inputs; thus, the basal ganglia have received considerable attention in the context of learning. Imbalances in activity across the basal ganglia nuclei within the motor circuit are associated with various motor disorders.

Detailed Description

This section considers on the motor aspects of the basal ganglia, which have been the focus of most computational studies. The articles can be classified as those concentrating on activity within particular areas of basal ganglia, those concerning basal ganglia function, and those about the roles of basal ganglia in motor disorders, predominantly parkinsonism.

Basal Ganglia Structure

While the structures of the basal ganglia (Fig. 1) appear to be common across a wide range of vertebrate animals, from primates to lamprey (Stephenson-Jones et al. 2011), there are somewhat different naming systems used in different species, and there are some structural differences across species (e.g., mammals versus birds). Following the nomenclature used in primates, the striatum, encompassing the caudate nucleus and the putamen, is the predominant recipient of

Basal Ganglia: Overview, Fig. 1 Major structures and pathways of the basal ganglia. Basal ganglia areas are colored in blue. Connecting arrows and lines represent the existence of direct synaptic interactions between areas. A projection from GPe to the striatum recently discovered in rats is omitted here

cortical inputs. There are several types of neurons within the striatum, most of which release the neurotransmitter GABA, which has an inhibitory effect on its targets (see entry ► [“Basal Ganglia: Striatal Models Cellular Detail”](#)). Striatal neurons are also major recipients of dopamine. Different types of dopamine receptors arise in different striatal neurons, and this variability translates into diverse impacts of dopamine release. In coarse terms, dopamine promotes activity in some striatal neurons and inhibits it in others, but specific effects may be more complicated and may depend on ongoing activity levels.

The substantia nigra has two main parts, the substantia nigra pars reticulata (SNr) and the substantia nigra pars compacta (SNc). The former sends inhibitory output to areas outside of the basal ganglia that may be related to oculomotor activity (see entry ► [“Basal Ganglia: Control of Saccades”](#)) or other motor activity, particularly in rodents. The latter releases dopamine to the striatum and other basal ganglia areas (see entry ► [“Basal Ganglia: Dopaminergic Cell Models”](#)).

The globus pallidus is also a dichotomous structure, with segments that are referred to as external (GPe) and internal (GPi). Both parts predominantly contain GABAergic neurons that exhibit high firing rates, although with diverse firing patterns, under baseline conditions (see entry ► [“Basal Ganglia: Globus Pallidus Cellular Models”](#)). The GPe receives projections from a subset of striatal neurons as well as from the subthalamic nucleus (STN), and it innervates both the striatum and the STN in return, although it appears that the subpopulations of GPe neurons targeting these areas are distinct (Mallet et al. 2012). The GPi is subject to inputs from a different subset of striatal neurons, from the STN, and from the GPe and in turn projects to thalamic areas outside of the basal ganglia.

The STN stands out as the only basal ganglia area that releases the excitatory neurotransmitter glutamate. STN neurons exhibit intrinsic firing, albeit with heterogeneous properties (see entry ► [“Basal Ganglia: Subthalamic Nucleus Cellular Models”](#)). Besides participating in a reciprocal loop with GPe (see entry ► [“Subthalamopallidal Loop and Oscillations”](#)), the STN projects directly to GPi. The STN also receives direct glutamatergic input from the cortex and some dopaminergic input from the SNc.

The routes along which activity flows through the basal ganglia have been classified into the direct pathway, the indirect pathway, and the hyperdirect pathway (Fig. 1). This nomenclature refers to the number and types of steps between the cortex, which provides input to the basal ganglia, and the GPi, the primary source of motor outputs from the primate basal ganglia. The direct pathway is the stream from the cortex to the striatum to GPi. In net, the direct pathway inhibits basal ganglia output, since the cortex excites the striatum, which inhibits GPi. Since GPi inhibits downstream areas, reductions in its output can be pro-kinetic. The indirect pathway goes from the cortex through the striatum to GPe and continues on to STN and then GPi; the GPe-GPi connection may also be included in this pathway. Overall, the indirect pathway is believed to promote basal ganglia output and hence suppress movement. This view is based

on the idea that the cortex excites the striatum and thus inhibits GPe and disinhibits its target STN, which in turn excites GPi; the reduction in GPe activity also lowers its inhibition of GPi, yielding additional enhancement of GPi firing. This reasoning omits the complication of feedback pathways, such as the excitation that STN sends to GPe, however. The hyperdirect pathway, like the direct pathway, includes only one intermediary between the cortex and GPi: it refers to the cortical projection to STN together with the STN link to GPi. Presumably, this pathway is called “hyperdirect” because it features excitatory transmission via glutamatergic synapses from STN to GPi that is faster and has a more immediate effect than the direct pathway’s inhibitory signaling via GABAergic synapses from the striatum to GPi. Like the indirect pathway, the hyperdirect pathway promotes basal ganglia output.

Finally, note that in rodent, which is a useful experimental model, the output structure analogous to the GPi is called the entopeduncular nucleus, and the major motor output structure is thought to be the SNr.

Basal Ganglia Function

The basal ganglia have been postulated to have a wide range of functions related to motor learning and other steps contributing to goal-directed movements (Chakravarthy et al., 2010). Models have been developed to represent and make predictions about the mechanisms involved in several of these functions. In the Basal Ganglia section of this encyclopedia, articles discuss background information and computational work on the mechanisms for action selection, habit formation, decision-making, and control of saccades. Furthermore, additional articles treat the role of the basal ganglia as an exploration engine and the learning and production of songs by birds.

Several lines of evidence point to the basal ganglia as a major site of action selection (see entry ► [“Basal Ganglia: Mechanisms for Action Selection”](#)). In particular, the basal ganglia are well positioned anatomically to orchestrate action selection by integrating inputs from a broad range of cortical areas and providing outputs to

downstream motor-related sites. The basic idea of how action selection might work rests on the observations that under rest conditions, the output nuclei of the basal ganglia, GPi and SNr, exhibit high activity levels and that these areas release inhibitory neurotransmitters, which are well suited to block motor activity. To perform a movement, this inhibitory “gate” must be opened but only in a way that allows the desired action while maintaining a blockade on all other movements. Models of action selection position the direct pathway as the agent that removes inhibition and suggest that the indirect and hyperdirect pathways can act to suppress behavior and to participate in behavior switching (see entry ► [“Basal Ganglia: Mechanisms for Action Selection”](#); Nambu et al. 2002).

Gradually, particular actions can become habits, which are actions that are elicited by certain stimuli in a way that lacks flexibility. Although established habits are less dependent on external rewards than are other learned behaviors, rewarding feedback that leads to striatal activation and associated plasticity of corticostriatal synapses are central to their being formed, and the corresponding learning process has been considered in computational models (see entry ► [“Basal Ganglia: Habit Formation”](#)). Dopamine is central to this form of plasticity and learning, and impairments in habit formation and performance are noted in subjects with Parkinson’s disease.

A basal ganglia function that is distinct from pure action selection and habit learning arises in perceptual decision-making. In this process, in abstract terms, it is thought that evidence favoring each of a number of choices accumulates until one option becomes sufficiently supported to elicit a corresponding behavior. The evidence is presumably represented by firing of various sets of cortical neurons that can influence basal ganglia activity, and basal ganglia activity is involved in setting the selection threshold (see entry ► [“Basal Ganglia: Decision-Making”](#)). In this view, the dopamine-based reward induced by a behavior is involved in threshold adjustment and thereby influences future choices. Computational models consider how the activity in the pathways of the

basal ganglia interacts with dopaminergic reward signals to drive and adjust the decision-making process, positing various roles for particular brain areas in evidence accumulation, stimulus detection, threshold adjustment, and decision-making and cancellation. Some also treat impairments in parkinsonian conditions and alterations under deep brain stimulation (see entry ► [“Basal Ganglia: Decision-Making”](#)).

Unlike other actions to which the basal ganglia contribute, rapid eye movements known as saccades in primates are gated by outputs from SNr rather than GPi. Issues under investigation relating to saccade generation, which have been treated in computational models, include mechanisms of target selection, of learning of target priorities, and of interactions of these processes with working memory (see entry ► [“Basal Ganglia: Control of Saccades”](#)).

A less thoroughly investigated function of the basal ganglia is the generation of variability in motor responses. Such variability is certainly observed in the behaviors of many species and seems to be essential for optimizing behavior and attaining maximal rewards. There is significant experimental evidence implicating the basal ganglia as a source of such motor exploration, and some computational modeling work to instantiate these ideas and study their implications has been performed (see entry ► [“Basal Ganglia System as an Engine for Exploration”](#)). In relevant models, while the direct pathway takes on the traditional role of implementing action selection, the indirect pathway, and particularly the STN, injects variability into this process. Learning based on reward signals is critical to such models and helps control the relative dominance of direct and indirect pathway signals.

One example of the prominence of behavioral variability arises in song production by songbirds. Songs must be learned, which involves exposure to the song of another bird, trial-and-error behavior, and auditory feedback. This process appears to heavily involve a basal ganglia analogue that participates in learning, in the introduction of behavioral variability, and in the selection of rewarding behaviors. Certain songbird experimental preparations are advantageous

for studying this combination of processes, and corresponding models of associated reinforcement learning and song production have been informed by observations from these preparations (see entry ► [“Basal Ganglia: Songbird Models”](#)).

Basal Ganglia and the Motor Symptoms of Parkinsonism

The loss of dopaminergic neurons in the SNc appears to be the critical trigger for a slew of changes in neuronal activity within areas of the basal ganglia that result in the motor symptoms of parkinsonism. This loss is typically gradual, and the causes appear to involve a complex combination of environmental and genetic factors that are still under intensive investigation.

Classical models of parkinsonism attribute its motor signs to an imbalance in direct and indirect pathway outputs stemming from the loss of dopaminergic input to the striatum (Albin et al. 1989). The loss of dopamine removes a source of excitation to the striatal neurons with D1 receptors, which project to GPi. Less firing by these striatal neurons, viewed as a weakening of the direct pathway, results in disinhibition of GPi. Meanwhile, diminished dopamine translates to reduction in inhibition of the striatal neurons with D2 receptors, which in turn inhibit GPe. As a result, GPe output is suppressed, which relieves GPe inhibition of STN and allows enhanced STN firing. The increased STN activity provides more drive to GPi, viewed as a strengthening of the indirect pathway. Together, these changes tip the balance of direct and indirect pathway effects in a way that favors the indirect pathway and promotes GPi activity. GPi outputs inhibit the pallidal recipient areas of the thalamus and are believed to represent an inhibitory gate that shuts down movement. Thus, pathologically enhanced GPi firing could interfere with initiating and carrying out movements in a way that translates into some motor signs of parkinsonism.

The complete explanation for the emergence of parkinsonian motor signs likely involves phenomena that are omitted from this classical description. It has become clear that loss of dopamine leads to widespread modifications of neuronal

activity patterns, rather than just changes in firing rates, in the basal ganglia. These effects include an enhanced prevalence of bursting, altered oscillation structure, and increased correlation in outputs of neurons within, and across, basal ganglia areas (Rubin et al. 2012).

One potential source of oscillations within basal ganglia is the reciprocal excitatory-inhibitory loop between the GPe and the STN (see entry ► [“Subthalamopallidal Loop and Oscillations”](#)). Oscillations in the beta band (broadly taken as 10–30 Hz) appear to be particularly prevalent in parkinsonian conditions and may be particularly effective at hijacking activity in thalamic areas downstream from the basal ganglia, and several different sources for such oscillations have been posited (see entry ► [“Basal Ganglia: Beta Oscillations”](#)).

While oscillations observed in the activity of basal ganglia neurons seem like a natural candidate to contribute to parkinsonian tremor, the link between altered neuronal firing and other parkinsonian symptoms may be less explicit. In particular, the slowing of movement known as bradykinesia may emerge from the interactions of all of the motor signaling pathways through the basal ganglia, or it may be necessary to consider basal ganglia interactions with corticospinal-muscular pathways to explain its source (see entry ► [“Basal Ganglia: Bradykinesia Models”](#)).

The predominant treatments for Parkinson’s disease in its early stages are pharmacological, aimed at replacing lost dopamine. In cases where pharmacological treatments gradually lose efficacy or induce substantive side effects, deep brain stimulation therapy represents a treatment option that, while highly invasive, is at least partially adjustable (by tuning of stimulation parameters) and reversible (by cessation of stimulation). Deep brain stimulation for Parkinson’s disease typically is targeted at STN or GPi and proves effective for many patients; although the mechanisms underlying its efficacy are not known, theories have honed in on its potential impact on patterns of basal ganglia activity and outputs and their downstream effects (see entry ► [“Computational Models of Deep Brain Stimulation \(DBS\)”](#); Rubin et al. 2012).

Bayesian Approaches in Computational Neuroscience: Overview

Ulrik R. Beierholm
 Psychology Department, Durham University,
 Durham, UK

Definition

Bayesian approaches in Computational Neuroscience rely on the properties of Bayesian statistics for performing inference over unknown variables given a data set generated through a stochastic process.

Detailed Description

Given a set of observed data $d_{1:n}$, generated from a stochastic process $P(d_{1:n}|X)$ where X is a set of unobserved variables, the posterior probability distribution of X is $P(X|d_{1:n}) = P(d_{1:n}|X)P(X)/P(d_{1:n})$ according to Bayes' theorem. X can be a set of fixed parameters as well as a series of variables of the same size as the data itself $X_{1:n}$.

Based on the posterior probability and a specified utility function, an estimate of X can be made that can be shown to be optimal, for example, by minimizing the expected variance.

One common use of this principle within computational neuroscience is for inferring unobserved properties (hidden variables X) based on observed data, d . These techniques can be used for inference on any data sets but has in neuroscience mostly been used for neurophysiological recordings, imaging, and behavioral data.

By their nature electrophysiological recordings are noisy and stochastic. Given the stochastic responses of neurons to stimuli, Bayesian methods can be used to infer the underlying stimuli or activation of the neurons, $X_{1:n}$ (Bayesian Electrophysiology Analysis).

For imaging data an underlying neural activity $X_{1:n}$, for example, firing rate at the level of individual columns of cortex, is assumed to give rise to measured responses $d_{1:n}$, for example, the blood flow measured by fMRI, through a stochastic process. Inverting the process through the Bayesian inference allows for estimating the unknown neural activity (Bayesian Imaging Analysis).

The ideas can also be useful for inferring properties about the behavior of individual human subjects, X , by the assumption of a stochastic process, $P(d_{1:n}|X)$, through which characteristics of each individual subject lead to individual choices in an experimental task, $d_{1:n}$ (Bayesian Behavioral Analysis).

The abovementioned techniques all use Bayesian inference to infer underlying properties of recorded data but are essentially used as very effective tools for data analysis. An alternative line of research takes as the working hypothesis that the human brain has evolved to the point of itself approximating an ideal Bayesian observer (sometimes referred to colloquially as the Bayesian Brain Hypothesis). Accordingly, this line of research compares human behavior to the output of such an ideal observer within, for example, perceptual (Bayesian Models of Perception) or cognitive tasks (Bayesian Models of Cognition).

A related effort has proposed that the computations necessary to perform the steps of Bayesian inference can be done through populations of biological neurons (Bayesian Inference with Spiking Neurons). Recent works on artificial neural networks have also reignited interest in combining ideas from the two areas of research including means of designing artificial networks able to perform Bayesian inference.

There is a continued effort to translate ideas on Bayesian inference from Machine Learning and Computer Science into Computational Neuroscience, including, for example, recent advances in sampling techniques for inference.

Biochemical Signaling Pathways and Diffusion: Overview

Kim T. Blackwell

Department of Bioengineering, George Mason University, Fairfax, VA, USA

Molecular Neuroscience Department, Krasnow Institute for Advanced Study, George Mason University, Fairfax, VA, USA

Detailed Description

Signaling pathways modulate the function of neurons and neuronal networks through diverse processes. The most well-known function of signaling pathways is synaptic plasticity, which controls neuronal networks via modulation of the strength of synaptic connections. Signaling pathways also are critical for neuronal development, axon guidance, and regulation of transcription and translation. Signaling pathways are activated by the G protein-coupled transmembrane receptors, such as metabotropic glutamate receptors or noradrenergic receptors; by the receptor tyrosine kinases; and by calcium influx through NMDA receptors or voltage-dependent calcium channels.

Calcium

Due to the importance of calcium, its concentration is tightly regulated by buffers and pumps. One of these calcium buffers, known as calmodulin, is not inert; rather, it can activate diverse enzymes such as adenylyl cyclase, calcineurin, phosphodiesterase type 1B, and calcium-

calmodulin-dependent protein kinase II. In addition to calcium influx through plasma membrane channels, both the mitochondria and the smooth endoplasmic reticulum (SER) are sources of calcium. Two types of calcium permeable channels reside on the SER: the inositol trisphosphate receptor channel and the ryanodine receptor channel. Calcium-dependent calcium release through these channels can lead to oscillations or waves of calcium, depending on various factors.

Kinases

The second messengers activated through transmembrane receptors have multiple downstream targets, including ionic channels, kinases, and phosphatases. Of the thousands of kinases and phosphatases in the proteome, several have a demonstrated role in synaptic plasticity, though their relative importance depends on the brain region and cell type. Protein kinase type C is a calcium- and lipid-activated kinase which is critical for LTP in the cerebellum. Protein kinase type A is a cAMP-activated kinase, which is critical for LTP in the striatum, and for several long-lasting forms of LTP in the hippocampus. Gene transcription and protein translation are required for both memory and for long-lasting forms of synaptic plasticity. One kinase that appears to bridge these other kinases and transcription is the ERK1/2 forms of MAPK (mitogen-activated protein kinase).

Modeling Techniques

Calcium dynamics and signaling pathways are modeled as cascades of biochemical reactions, both bimolecular reactions and enzyme reactions, and diffusion. Many special purpose simulators are available to implement these signaling pathways, either using stochastic techniques or deterministic approaches. Modeling calcium influx requires the simulator to have capabilities for modeling membrane potential. Due to the diversity in temporal and spatial scale involved in modeling neuronal electrical activity coupled to reaction-diffusion pathways, very few models

incorporate signaling pathways in entire neurons, though the number of such models is increasing as computational power increases.

Functional neuroimaging

Definition

Brain imaging constitutes a set of techniques used to measure functional activity in networks of interacting brain cells as well as to reveal the major underlying structural properties of these networks. Functional data obtained with these techniques reflect local changes in brain perfusion, metabolism, and extracellular electric/magnetic potentials originated from the activity of these brain cell networks. Brain imaging has been traditionally used to explore both normal and pathological brains in a large variety of species ranging from rodents to primates. In principles, brain imaging could be applied for both in vitro and in vivo situations.

Detailed Description

Techniques for brain imaging have been developed for two major physical brain scales, i.e., the mesoscale and the macroscale. Theoretical models useful to interpret how these two physical scales interact have been developed in the past (see ► [“Multiscale Brain Connectivity”](#)). Brain imaging modalities have been combined with specific stimulation techniques to study brain activity in both mesoscopic (e.g., uncaging methods, optogenetics – see ► [“Optogenetics”](#)) and macroscopic (e.g., transcranial magnetic stimulation, TMS) levels. Brain imaging constitutes one of the most important building blocks in the development of brain-machine interfaces (see ► [“Brain-Machine Interface and Neuroimaging”](#)).

Neuroimaging at the Mesoscale

Functional refers to observations reflecting the activity of populations of cells (e.g., neurons, astrocytes) in a particular brain structure with the resolution of single cells. Examples of functional neuroimaging for this particular scale are confocal/multiphoton (MP) microscopy, current source density (CSD) analysis from intracranial recordings using MEA, intrinsic optical signal (IOS), optical coherence tomography (OCT), and

voltage-sensitive dye imaging (VSDI). These imaging techniques are based on either in vitro or very invasive in vivo experimental protocols. Some of the imaging techniques based on optical phenomena (confocal/MP microscopy, VSDI – see ► [“Voltage Sensitive Dye Imaging, Intrinsic Optical Signals”](#)) provide the ideal spatial resolution to explore the activity of single cells, but their temporal resolution is in the order of hundreds of milliseconds. In contrasts, images resulting from the CSD analysis could reflect electrical phenomena happening in the order of a few milliseconds, but they are associated with the activity of synchronized population of neurons in extended brain regions. IOS and OCT are employed mainly to record changes in blood flow/volume in the brain as well as alterations in blood oxygen concentration (see ► [“Voltage Sensitive Dye Imaging, Intrinsic Optical Signals”](#)).

Anatomical refers to static pictures of the cellular networks directly reflecting structural properties. These images are obtained using different modalities of sectioning microscopy (see ► [“Physical Sectioning Microscopy”](#)).

Neuroimaging at the Macroscale

Functional refers to observations reflecting the activity of large regions inside the brain. Examples of functional neuroimaging for this particular scale are functional magnetic resonance imaging (fMRI), positron emission tomography (PET), single-photon emission tomography (SPECT), functional near-infrared spectroscopy (fNIRS), and electro (EEG)/magneto (MEG) –encephalograms. The spatiotemporal profiles of these brain imaging techniques are quite different (Riera and Valdes-Sosa 2010). Deciphering the origin and nature of signatures in the functional neuroimaging imprinted by abnormal brain activity is important while using them for diagnosing, monitoring, and treating brain diseases and disorders (see ► [“Connectivity Analysis in Normal and Pathological Brains”](#)). To that end, it is crucial to understand the physiological mechanisms underlying these brain imaging techniques (see ► [“Biophysical Models: Neurovascular Coupling, Cortical Microcircuits,](#)

[and Metabolism,”](#) ► [“Kinetic Models for PET/SPECT Imaging,”](#) and ► [“Forward and Inverse Problems of MEG/EEG”](#)). These techniques classify either as slightly invasive (i.e., fMRI, fNIRS, EEG/MEG) or extremely invasive because of the use of radioisotopes (i.e., PET, SPECT, see ► [“Radiopharmaceuticals in Molecular Imaging”](#)). A variety of methods have been developed for the preprocessing and analysis of brain imaging data, with resulting software and platforms currently available (see ► [“Software for Neuroimaging Data Analysis,”](#) ► [“Statistical Analysis of Neuroimaging Data,”](#) and ► [“Meta-analysis in Neuroimaging”](#)).

Anatomical refers to static pictures of the entire brain, or part of it, directly reflecting structural properties. Example of imaging modalities used to study morphometric characteristics of brain tissues are the T1/T2 magnetic resonance imaging (MRI) and the computed tomography (CT). Diffusion tensor imaging (DTI) has been commonly employed to study the strengths of connections between different brain regions.

Definition

A brain-machine interface (BMI) is a direct communication pathway between the nervous system and a man-made computing device. This communication is *unidirectional* in BMIs that either record neural activity in the nervous system to affect the state of an external device or stimulate neural activity to affect the state of the nervous system. It can also be *bidirectional*, such as BMIs that record activity from certain parts of the nervous system and use this activity – or features extracted from it – *in real time* to stimulate activity in other parts of that system. This communication can occur at multiple levels, which may include muscles, peripheral nerves, spinal cord, or the brain.

Detailed Description

BMIs fundamentally rely on the concept of causation between electricity and movement or between electricity and cognition. The causal link between electrical current injection into the body and movement of parts of that body was first established in the late eighteenth century by Galvani (1791), Fowler and Galvani (1793), who could evoke muscle twitches in the frog legs by direct current injection into the muscle *ex vivo*. A similar discovery in the central nervous system was made in 1870 by Fritsch and Hitzig (1870), in which electrical stimulation of different areas of the cerebral cortex caused muscular contractions of specific parts of a dog's body *in vivo*. It was not until 1928 that recording of the all-or-none electrical discharge of single neurons in the optic nerve of the toad was made by Adrian (Adrian

and Bronk 1928) and was found to be strongly correlated with light stimuli. Ever since, countless studies have revealed numerous mechanisms of neural coding of sensory stimuli or movement parameters, such as orientation tuning by V1 neurons (Hubel and Wiesel 1962), spatial position by hippocampal place cells (Ranck 1973; O’Keefe 1979) and movement direction by primary motor cortex neurons (Georgopoulos et al. 1986).

The early 1990s nonetheless has witnessed a paradigm shift in the way recording and stimulation of neural activity is achieved. In particular, micro-wire bundles have been used to record the activity of a handful of neurons in awake behaving animals (McNaughton et al. 1983). Striking advances in the microfabrication technology of high-density micro-electrode arrays (HDMEAs) (Drake et al. 1988; Normann et al. 1999) have later permitted large-scale simultaneous recording of many neurons (tens to hundreds) in awake behaving subjects, which eventually paved the way for these arrays to become a key element in BMIs development in subsequent years (Nicolelis 1999).

Unidirectional BMIs

Afferent BMIs

Afferent BMIs (ABMIs) rely on transforming features of sensory stimuli (e.g., auditory, visual, etc.) to electrical pulse trains in order to stimulate neural activity in the central or the peripheral nervous systems to cause artificial sensation to compensate for some form of sensory loss (e.g., deafness or blindness) (Fig. 1). Auditory prosthesis, such as cochlear implants (CIs) – dating back to the first implant in 1957 by Djorno and Eyries – is the first example of an afferent BMI that was approved by the FDA in 1984 (House and Urban 1973). CIs transform sound features (e.g.,

intensity or pitch) recorded through a microphone to pulsatile currents in the spiral ganglia. This eventually elicits action potentials from residual hair cells in the auditory nerve of hearing-impaired subjects.

Likewise, visual prosthesis rely on transforming features of the visual scenes recorded through a video camera to stimulate different parts of the visual pathway in legally blind subjects. The site of stimulation along this pathway is a function of where neural degeneration occurs, but the most promising demonstration of visual prosthesis thus far has been through the stimulation of the retinal ganglion cell layer that provide input to the optic nerve in patients with retinitis pigmentosa and age-related macular degeneration (de Balthasar et al. 2008).

Efferent BMIs

EBMIs rely on extracting features from recorded neural activity in real time that are subsequently transformed into control signals for actuating an external device (e.g. a paralyzed limb) (Fig. 2). They can be categorized based on the recorded signal modality, which is predominantly neural (but see (Sitaram et al. 2009) for an example of metabolic activity that utilizes blood-oxygen-level dependent (BOLD)).

In EBMIs, the neural readout may differ in the temporal and spatial scales of variations, as well as in information content, as shown in Fig. 3. While the 1–2 ms APs elicited by individual neurons are known to contain large information about behavioral covariates (typically measured in bits per second), they tend to be highly variable and can only be recorded thus far using penetrating microelectrodes (McNaughton et al. 1983; Drake et al. 1988; Normann et al. 1999; Nicolelis 1999), or using voltage-sensitive dye-based calcium imaging at shallow cortical depths (Koester and

Brain-Machine Interface: Overview, Fig. 1 Basic elements of an afferent BMI. Features are extracted from the sensory stimuli and then converted to electrical pulses that

stimulate target areas in the afferent pathway of the corresponding sensory modality

Brain-Machine Interface: Overview, Fig. 2 Basic elements of an efferent BMI. The read out of neural activity can be a single signal source recorded from a target area within an efferent pathway – or multiple sources fused

together within the transform block, aka the “decoder” – to actuate an artificial device. The user is able to continuously monitor changes in the state of the actuator in real time, typically through visual feedback

Brain-Machine Interface: Overview, Fig. 3 Spatial, temporal, and information characteristics of neural signals recorded from the brain for efferent BMI operation. (Adapted from Oweiss 2010)

Sakmann 2000; Stosiek et al. 2003) – although the latter signals have not been used in BMIs. While local field potentials (LFPs) can also be recorded using penetrating electrodes, they contain less information than spike trains and are believed to provide a glimpse over the synchronized activity of large populations of neurons within a few 100 microns from the electrode tip (Mitzdorf 1985; Katzner et al. 2009). Macroelectrodes, either implanted subdurally to record ECoG or fixed extracranially to record surface EEG, offer another less risky alternative for EBMI since they are less- or noninvasive (Wolpaw et al. 2002; McFarland et al. 2005; Thongpang et al. 2011).

Historically, work in efferent BMIs (EBMIs) is more recent than ABMIs. The first EBMI dates back to the pioneering work of Fetz (1969) and was based on a single-neuron recording from a monkey’s precentral “motor” cortex. In this setting, the BMI was a single-input/single-output (SISO) system where the firing rate of a single neuron was integrated over small time intervals and used to control an illuminated meter whose pointer deflection was proportional to the activity integrator’s output. The animal had to volitionally modulate the firing rate of the selected neuron in order to bring the meter to a predetermined

threshold for reward. This operant conditioning paradigm constitutes the first proof of concept of an EBMI, though was not used to actuate any limbs. This approach has been extended in modern EBMIs to involve the simultaneous recording and use of hundreds of neurons that are subsequently transformed through a “decoding” filter to generate control signals that actuate multiple degrees of freedom (DOFs) (Hochberg et al. 2012). As such, these BMIs are considered multi-input/multi-output systems (MIMOs).

Cerebral BMIs

Another class of unidirectional BMIs – neither designed to directly cause sensation nor produce movements – is designed to stimulate neurons in the central nervous system to directly inhibit pathological behavior in subjects with neurological impairment. An example of such systems is deep brain stimulators (DBS), in which an electrode array is implanted in the subthalamic nucleus (STN) of a Parkinsonian patient, and macrostimulation of the STN through a few electrode leads ameliorates the disease symptoms by reducing bradykinesia and tremor (Coffey 2009). Similar designs are intended to regulate mood disorders (Mayberg et al. 2005; Hajcak et al.

2010) or abate epileptic seizures (Theodore and Fisher 2007; Halpern et al. 2008; Boon et al. 2009; Jones 2010).

Bidirectional BMIs

Bidirectional – or sometimes referred to as “recurrent” – BMIs differ from unidirectional BMIs in that neural measurements are used in the input to the transform to compute stimulation parameters *in real time*. As such, they are considered “closed loop” compared to unidirectional BMIs that are “open loop.” This specific feature allows stimulation to be dynamic and to follow the dynamics of the neural input to the transform, which may be volitionally modulated by the subject in certain applications (Fig. 4).

Sensorimotor BMIs

This class of bidirectional BMIs combines recording and stimulation to restore one or more functions. For example, motor signals can be recorded from cortical areas and used to directly control muscle contraction or hand grasp via FES (Moritz et al. 2008; Ethier et al. 2012). These signals can also be used to stimulate the spinal cord below the injury site using parameters extracted from cortical signals in real time (Harkema et al. 2011; Moritz et al. 2007; Shanechi et al. 2014) or via stimulation of peripheral nerves (Navarro et al. 2005; Micera and Navarro 2009). In that respect, this is a class of bidirectional BMIs that restores motor function through FES.

Another class of bidirectional BMIs combines efferent and afferent BMIs to restore movements as well as sensory feedback in the form of touch and proprioception. The importance of such

design is the indispensable role that somatosensation plays in the integration and coordination of limb movements, particularly for complex upper limb functions such as reaching and grasping. There is debate over which site(s) to stimulate to restore somatosensory feedback, but the majority of approaches have focused on stimulation of peripheral nerves (Raspovic et al. 2014). Peripheral stimulation, however, is not feasible in patients with spinal cord injury (SCI). Recent reports devised protocols for these patients based on subcortical (Daly et al. 2012; Liu et al. 2011) or cortical stimulation (Berg et al. 2013; Tabot et al. 2013).

A third class of bidirectional BMIs aims to induce plastic changes in neural circuits by using patterns of activity recorded from one brain site to stimulate activity in another distal brain site in real time (Jackson et al. 2006). Key to induce this plasticity is to ensure stimulation is delivered within a few milliseconds of recording spike events so as to promote LTP and LTD of synaptic connections, consistent with Hebbian plasticity (Hebb 1949). It is contended that this type of plasticity triggers functional as well as structural changes in the targeted neural circuits (Lucas and Fetz 2009); the longevity of this plasticity, however, is yet to be demonstrated, since neurons return to their original encoding properties shortly after stimulation is terminated.

Cognitive BMIs

Certain brain areas have specific cytoarchitectonic architecture with known role in cognitive functions, such as the hippocampus role in the formation and maintenance of long-term episodic memory (Bliss and Collingridge 1993). This knowledge is critical to the ability to restore

Brain-Machine Interface: Overview, Fig. 4 Basic elements of a bidirectional – or recurrent – BMI. Neural activity is read out to control an actuator. In turn, changes in the actuator state are measured and used to provide

information back to the nervous system through stimulation patterns of relevant areas in the peripheral nerve, the spinal cord, or the brain

inter-areal as well as intra-areal information exchange by means of artificial devices. In this setting, neural activity is recorded from one upstream region (e.g., hippocampus CA3) known to provide feedforward information to downstream regions (e.g., CA1) (Yeckel and Berger 1990). When the communication between the two regions is disrupted due to malfunctioning neural tissue, eventually causing memory loss, activity recorded from CA3 is “decoded” to predict the input to the CA1 region. The BMI then uses this prediction to derive the stimulation patterns needed to evoke biomimetic activity at the output of the CA1 region. Thus, the transform model in this BMI design lumps both a “decoder” of the input neural activity in CA3 and an “encoder” of the patterns to be evoked in CA1 through stimulation in one block (Song et al. 2007).

Bidirectional BMIs for Neurological Disorders

This class of BMIs extends cerebral BMIs to include a closed loop design that records neural activity and uses features extracted from this recordings to dynamically adjust stimulation patterns in real time (Rosin et al. 2011) (Carlson et al. 2013; Afshar et al. 2012). A similar approach is used to reduce or prevent seizures from occurring in drug-resistant epileptic patients (Nagel and Najm 2009) (Morrell and RNS System in Epilepsy Study Group 2011). This strategy is more advantageous compared to resection of the parts of the brain where hypothesized epileptic foci reside, which has been the standard clinical treatment for many years. Other examples use a similar concept to treat brain injury or psychiatric diseases, such as traumatic brain injury (Schiff et al. 2007), major depression (Malone et al. 2009), obsessive compulsive disorders (Goodman et al. 2010), among others (Mohr 2008).

The Computing Device

A key element in BMI design is the computational capability of the device and the corresponding number of inputs and outputs. For example, in SISO BMIs, computations can be as simple as

the detection of APs presence in a noisy electrode recording followed by a spike count within a fixed time interval (usually 50 ms). They can also consist of complex time varying (Kalman 1965) – and sometimes nonlinear (Hampson et al. 2013) – transformation of multiple electrode recordings in MIMO BMIs. EBMIs in particular are designed to have the decoder extract neural features (typically the firing rate of individual cells) to determine the “state” of the population. Because this state varies in time, it can be described by a “trajectory” in a neural state space (Oweiss 2010; Badreldin et al. 2013; Churchland et al. 2012). The transform then filters this state to reduce its dimension to a smaller number of variables that can be subsequently used to control the actuator (Gilja et al. 2012). As such, the subject is required to learn this transformation with extended practice.

Likewise, in ABMIs, the computing device extracts features from signals measured in the outside world to influence the “trajectory” of the stimulation parameter(s) in a stimulation parameter space. Because the mapping between the trajectory of natural stimuli in the task space and the evoked response in the neural state space – which is typically of much higher dimension – is unknown, methods for finding the “best” stimulation strategies in “open loop” BMIs are far from optimal. As such, the experimenter/clinician assumes the role of finding an optimal “tune-up” of stimulation parameters to restore a specific function by trial and error. For example, stimulation parameters (e.g., pulse frequency) in DBS systems are manually adjusted to fit each patient and reduce tremor (Kuncel et al. 2006). The lack of selectivity of electrical stimulation and the absence of knowledge of the dynamics of the neural circuits affected by stimulation, however, make this approach a real challenge. As such, characterizing the dynamics of stimulation-evoked neural activity in upstream or downstream circuits becomes important in order to optimize the stimulation “dose” for restoring a desired function and to minimize any side effects over the long term (Liu et al. 2010, 2011; Kuncel et al. 2008). Thus, studying the neural system being stimulated by an artificial device may offer advantages in clinical BMI applications.

Brain-Scale Networks: Overview

Theoden I. Netoff
Department of Biomedical Engineering,
University of Minnesota, Minneapolis, MN, USA

Definition

The brain is composed of many neurons, functional areas, and layers. Together these components work as a network to produce behavior. At minimum, the network behavior is determined by four things: (1) the network inputs, (2) the dynamics of the individual nodes, (3) the coupling functions between the nodes, and (4) the topology. This encyclopedia section will provide a brief overview on characterizing brain-scale networks. Often the coupled system will have emergent behaviors, behaviors that could not be predicted from analysis of the individual components alone. Understanding how the brain functions requires an understanding of how components work together in a network. In many diseases the cause cannot be pinpointed to dysfunction or

failure of a single component, such as an ion channel mutation. Instead, subtle changes in cellular behavior may lead homeostatic mechanisms to alter the coupling between the neurons and brain areas, resulting in pathological activity such as synchronous population oscillations or unchecked excitability. The ultimate goal in applying the network theory to understanding connections within the brain is to develop a measure that can explain the emergence of pathological behaviors and to perhaps develop approaches to treating diseases.

But first, we will introduce a few common terms. A **network** is a collection of coupled components. Generally, when the components coupled together are different elements, it is referred to as a **system**. If the components of the system are similar and interchangeable, it is instead called a **network**. The components in the network are referred to as **nodes**, which can be individual neurons or brain regions. The coupling between the nodes is referred to as **edges**, which can be synapses or fiber paths. Coupling in the nervous system is generally through chemical synapses which are **directional**, where the coupling of neuron or region A onto B will be different than B onto A. However, for networks of neurons coupled through electrical synapses, the coupling can be undirected. Networks are considered **weighted** if the strengths of coupling between nodes have a distribution and **unweighted** if they are all the same.

Generally, the dynamics of the nodes and coupling function are highly nonlinear. A **linear response** is defined as given twice the input, the output will be twice as strong. However, because neurons have thresholds and synapses are plastic, the responses are very nonlinear. Furthermore, neurons are a mixture of **deterministic** behavior, where its behavior can be determined from its past and its inputs, and **stochastic**, where the activity is also due to some noise in the system which cannot be accounted for.

The statistics of the coupling within a network is called the **topology**. A list of all the connections within a network is called the **graph**. If nodes have a physical location in space, such as brain regions, and coupling is dependent on the

distance, the network is considered to have a **geometry**.

In summary, neuronal networks are nonlinear, directional weighted graphs with a geometry. These networks are called complex networks, and few tools have been developed to analyze them. The development of these network analysis tools is at the cutting edge.

Detailed Description

The goal of these encyclopedia entries is to provide an introduction into the network theory. In the first entry (► [“Network Theory in Neuroscience”](#)), there is an overview of the network theory and its applications to diseases. In ► [“Functional Network Observations of Diseased Brain States,”](#) there is an introduction to functional networks in neuroscience. In ► [“Determining Network Structure from Data: Nonlinear Modeling Methods,”](#) we will introduce methods for reconstructing networks from the data using nonlinear measures. In ► [“Master Stability Function for Globally Synchronized Systems,”](#) we introduce a universal approach to determining if a network will synchronize given the dynamics of the individual components and the network topology, through the analysis of the master stability function. In ► [“Connectionist Models of CPG Networks,”](#) we will provide an introduction to non-synchronous network behaviors, such as seen in central pattern generators. In ► [“Neuropathologies and Networks,”](#) we will introduce pathological network function to characterize diseases.

Brainstem Processing: Overview

Robert Butera¹ and Kendall Morris²

¹School of Electrical and Computer Engineering, Laboratory for Neuroengineering, Georgia Institute of Technology, Atlanta, GA, USA

²College of Medicine, Molecular Pharmacology & Physiology, University of South Florida, Tampa, FL, USA

Detailed Description

The brainstem has received considerably less attention by computational neuroscientists than other regions of the mammalian brain. This section highlights key areas that have received attention: neural circuitry underlying the generation and control of the respiratory rhythm, the baroreflex underlying the regulation of blood pressure, and pathways for pain processing. Entries in this section cover all three of these areas.

The article titled ► [“Baroreflex Models”](#) reviews over two decades years of computational models focused on neural pathways where blood flows in response to pressure changes in the circulatory system mediated by the baroreflex pathway.

Much attention has been given to the modeling of respiratory rhythm generation. The generation

and control of breathing is covered by two entries in this section. The entry titled ► [“Pre-Botzinger Complex Rhythm Generation”](#) surveys computational models of rhythmic activity in the pre-Bötzinger complex, which underlies the inspiratory component of respiratory rhythm generation and is a central pattern-generating circuit itself when isolated. The article titled ► [“Control of Breathing, Integration of Adaptive Reflexes”](#) describes computational models of adaptation and plasticity of the respiratory rhythm in response to external perturbations. There are also relevant articles in other sections of this encyclopedia, including ► [“Computational Models of Mammalian Respiratory CPG”](#) and ► [“Brainstem Motoneurons, Models of”](#).

The area of pain processing has received much less attention by computational neuroscientists. The article titled ► [“Pain Processing Pathway Models”](#) summarizes computational efforts in this area.

Cable Theory: Overview

William R. Holmes
Department of Biological Sciences, Ohio
University, Athens, OH, USA

Detailed Description

Cable theory has a prominent place in neuroscience as it forms the basis of models of single neurons, axons, and dendrites and has led to an

understanding of intraneuronal signaling. Starting with the conceptual model of a patch of membrane as an electric circuit, application of basic principles from physics leads to a mathematical equation, the cable equation. We start this section with an article on the cable equation, discussing the history of the cable equation in neuroscience, showing the derivation of the cable equation, providing solutions for the infinite cylinder, steady-state solutions for semi-infinite and finite cables and branched dendritic trees and transient solutions, concluding with a discussion of insights from cable theory. Several parameters play key roles in intraneuronal signaling including membrane capacitance, axial resistivity, the space (length) constant, and the time constant, and there are articles on each of these topics. From there we have two articles describing work done by Wilfrid Rall, widely regarded as the father of computational neuroscience. The first describes how Rall applied cable theory to dendritic trees and showed that given certain conditions a highly branched dendritic tree could be reduced mathematically to an equivalent cylinder. The simplicity and elegance of the equivalent cylinder model permitted mathematical analyses and insights regarding signaling in otherwise morphologically complex dendritic trees. The second describes various formulas Rall derived to estimate the electrotonic length of dendritic trees from simple voltage transients, formulas that have been applied in hundreds of studies. Finally, there are three articles that discuss extensions of cable theory in various ways. The first presents the morphoelectrotonic transform, a procedure that addresses the issue that attenuation of voltage from a synaptic input from the dendrite to the soma is not simply given by the electrotonic distance because of the effect of boundary conditions. The morphoelectrotonic transform provides a graphical means to visualize voltage attenuation both toward the soma and away from the soma, directly and intuitively. The second introduces the continuum theory for modeling dendritic spines. While there are various ways to incorporate the effect of dendritic spines in models, the continuum theory describes a novel way of doing this within the cable equation. Lastly, insights can be obtained from the

quasi-active approximation of a nonlinear cable. Here classic passive cable theory is extended by linearizing voltage-dependent conductances around a given membrane potential cable allowing the effect of voltage-dependent conductances on dendritic filtering to be studied mathematically. Almost all of these articles assume membrane is passive, but it is clear that both dendrites and axons contain voltage-dependent conductances. Nevertheless, cable theory is important for providing a basic understanding of intraneuronal signaling that forms the basis for understanding what happens with active conductances.

Cerebellum: Overview

Fidel Santamaria
UTSA Neurosciences Institute, The University of
Texas at San Antonio, San Antonio, TX, USA

Definition

The cerebellum processes sensory and motor information. Structurally is divided in the cerebellar cortex network and the deep cerebellar nuclei. Inputs to the cerebellar cortex arrive via the mossy fibers from multiple sources; mossy fibers contact granule cells, Golgi cells and unipolar brush cells. The second input to the cerebellar cortex comes

from the inferior olive in the form of climbing fibers that synapse Purkinje cells. The output of the cerebellar cortex is provided by Purkinje cells that integrate the synaptic activity of climbing fibers, granule cells, and inhibitory interneurons. Golgi cells provide an inhibitory feedback mechanism to the granule cell layer. The deep cerebellar nuclei are the final integrator of cerebellar information. Cells in the deep cerebellar nuclei receive input from Purkinje cells, mossy fibers and climbing fibers.

Detailed Description

Cerebellar Cortex

The widely studied cerebellar cortex is composed, mainly, of four types of neurons: Granule cells, Purkinje cells, inhibitory interneurons (stellate and basket), and Golgi cells. There are two inputs to the cerebellar cortex provided by mossy fibers and climbing fibers. Climbing fibers are axons from inferior olivary neurons. Mossy fibers are a collection of axons from multiple areas that can carry direct sensory or cerebro cortical information. The arrangement of the cerebellar cortical neurons is regular across the cortex. Mossy fibers contact granule cells and Golgi cells. Granule cells send an axon into the molecular layer that bifurcates. The bundle of bifurcated axons is known as the parallel fibers. Parallel fibers contact Golgi cells, inhibitory interneurons and Purkinje cells as they traverse the cerebellar cortex. Climbing fibers synapse onto Purkinje cells.

The particular arrangement of granule cell-to-Purkinje cell connectivity was very attractive to computational scientist early on. The ‘Beam Hypothesis’ stated that a focal stimulation of the granule cells would be transformed into a sequential activation of Purkinje cells along the path of the parallel fibers (Braitenberg and Atwood 1958). The evoked inhibitory activity from parallel fiber to inhibitory interneurons would reduce the activity of the Purkinje cells on either side of the beam of activated Purkinje cells. The feedback mechanism provided by Golgi cells on to granule cells would then reduce over-excitability. The central mechanism of information processing in

this model is the existence of a beam of activated Purkinje cells following the local stimulation of granule cells.

The lack of beams of Purkinje cell activity reported by multiple teams over the years has prompted a discussion on how the cerebellar cortex processes information. Several reports have shown that Purkinje cells are activated only when they are directly above the cluster of stimulated granule cells. The Purkinje cells along the parallel fiber path are either inhibited or show no change in firing rate. Experimental and computational evidence has shown that this is due to fast feed-forward inhibition from the inhibitory interneuron on Purkinje cells concomitantly stimulated by parallel fibers. In fact, blocking of inhibition reveals a beam of Purkinje cell activity as predicted by the Beam Hypothesis (Santamaria et al. 2007). Thus, the emergent understanding is not that different from a center surround receptive field model. Under this perspective, granule cell synapses are effective in driving Purkinje cells to fire only when the Purkinje cells are close to the site of stimulation. Parallel fibers provide excitatory and feed forward inhibitory input to Purkinje cells far from the site of stimulation without this stimulation being reflected in changes of the Purkinje cell firing rate. However, the dendritic stimulation results in activation of voltage sensitive calcium channels and calcium activated potassium channels, modifying the excitability of the dendrite. This dendritic activation can then modify the response of the Purkinje cell to direct granule cell stimulation. Therefore, the long range effect of parallel fibers is to provide contextual information.

The Purkinje cell was one of the first neurons to be studied using the compartmental modeling approach. The large amount of information on somatic and dendritic conductances permitted to develop detailed compartmental models. These models have been reused and enhanced over the years to study different aspects of cerebellar function (De Schutter and Bower 1994; Steuber et al. 2007). There are also several models of inhibitory interneurons, Golgi cells and granule cells. Recent work suggests that the Purkinje cell might be simplified to a perceptron (Clopath et al. 2012).

Synaptic Plasticity

Long term depression (LTD) in the parallel fiber-to-Purkinje cell synapses is a model of learning and memory (Ito 2006; Feil et al. 2003). LTD is induced by the concomitant activation of the climbing fiber input and stimulation of a small bundle of parallel fibers. It is widely assumed that the climbing fiber stimuli carries a training or error signal, while the encoding signals, e.g., motor command, is encoded in the parallel fiber activity. The biochemical transduction cascade is very well understood and has been modeled using mass action and Monte Carlo models (Doi et al. 2005). These models and their experimental tests have pointed out to positive feedback biochemical loop that triggers and sustains LTD. Briefly, LTD is induced by the influx of calcium ions through voltage sensitive channels and release from intracellular stores. Calcium ions activate protein kinase C (PKC) which eventually activates mitogen associated protein kinase (MAPK). MAPK interacts with other substrates to produce arachidonic acid which in return activates more PKC. PKC then continues working in the feedback loop or phosphorylate AMPA receptors. Phosphorylated AMPA receptors are then internalized and the synaptic strength is reduced. The activation of the feedback loop is not a linear integrator of calcium concentration, instead it acts as a leaky integrator, thus the total amount and the temporal release of calcium determines the expression of LTD (Tanaka et al. 2007; Xia et al. 2000).

Other Cells in the Cerebellar Cortex

There are other types of cells not traditionally included in cerebellar models. Lugaro cells are interneurons that are located in the granule cell layer (Lainé and Axelrad 1996). These neurons receive input from Purkinje cells and could be connected among themselves with gap junctions. These cells seem to be inhibitory and hypothesized to work in the burst frequency response of the granule cell layer. Another type of neuron,

primarily located in the vestibulo cerebellum, is the unipolar brush cell. These cells receive inhibitory inputs from Golgi cells and excitatory inputs from mossy fibers. Unipolar brush cells have multiple excitatory targets in the granule cell layer (Mugnaini and Floris 1994).

The Deep Cerebellar Nuclei

The deep cerebellar nuclei (DCN – dentate, interpositus, and fastigii) receive inhibitory inputs from Purkinje cells and excitatory activity from mossy fibers and climbing fibers. The cell from the cerebellar nuclei generates the bundles of axons that go to other areas of the brain. The cells of the DCN can be thought as the final and global integrator of the input and output signals to the cerebellum. DCN cells integrate inputs from the brain stem, inferior olive, and spinal cord with the Purkinje cell output from the cerebellar cortex. There are excitatory and inhibitory DCN neurons with their electrophysiological and computational contributions still being studied. The precise spike timing control of DCN spiking by Purkinje cell is believed to be the mechanism of the precise motor skills (Gauck and Jaeger 2000).

Summary

Although the function of the cerebellum is still being debated, how it processes information is becoming clearer due to vast amount of experimental information from ultra-structure to electrophysiology and behavior. Altogether, this large amount of data allows computational scientist to build realistic models at different levels of detail that can be experimentally tested.

Definition

Computational neuroanatomy is a subfield of neuroscience that aims to create functionally and structurally accurate models of the nervous system. These models are based on a wide range of input data, including microscopy and electrophysiology. These data acquisition methods encompass the broad scales across which neuroanatomy plays a role: (1) nanostructure describing individual connections between cells, (2) microstructure describing neuronal shape and cell type, and (3) gross structure describing cross-brain connectivity patterns. Computing in this field draws largely from the need to synthesize multiple modalities to statistically generate accurate models of morphology. For example, properties such as morphological structure, connection topology, wiring principles, and growth rules are statistically drawn from multiple sources and combined into motifs representing large-scale connectivity. High-performance computing can then be leveraged to simulate and verify the resulting models, with the end goal of studying neural behavior in silico.

Detailed Description

Computational neuroanatomy deals with the development of structural and functional models

of the nervous system. The structural data forming the basis for these models are collected across multiple scales using a variety of data-acquisition and imaging modalities. Electron microscopy is used to acquire ultrastructural information of synapses, axon terminals, and dendritic spines at the nanometer scale. Advances in serial sectioning electron microscopy have enabled the investigation of whole neurons at this scale, with large-scale efforts focused on three-dimensional reconstruction. Optical microscopy (bright field and fluorescence) is often leveraged at the micrometer scale to study neuronal morphology, local circuits, and long-range projections. Both physical and optical sectioning is routinely used to obtain 3D volume data. Magnetic resonance imaging (MRI) and other noninvasive techniques are frequently employed for mapping cortical areas, major nuclei and fiber tracts, as well as functional data across the entire brain network.

Topics of study in computational neuroanatomy focus largely on model reconstruction and generation. This includes data mining from multimodal images using segmentation algorithms, morphometry, and statistics. This raw reconstructed data must also be analyzed to establish fundamental rules for constructing viable large-scale models. This requires topological analysis (small world, scale-free, etc.), growth and development models, organizational and optimization principles (e.g., wiring length minimization, self-organization, etc.), representation and ontology, and neuroinformatics. In addition, tools must be designed to enable viable exploration of neuroanatomical structures across multiple scale, integrating visualization, and comparative analysis. One of the major goals of comparative tools is the study of diseased versus healthy neuroanatomy, as well as inferring function from structure. Early studies in computational neuroanatomy, especially at the cellular level, were strongly motivated by the need for morphologically detailed multicompartmental models for use in neuron simulators such as NEURON (Carnevale and

Hines 2006), GENESIS (Bower and Beeman 2012), and others (Ascoli 2002).

Overview of Chapters

The computational neuroanatomy section features chapters that touch upon the topics listed above. The chapters can be roughly grouped into four categories: (1) brain atlases and the connectome, (2) imaging, (3) geometric reconstruction, and (4) wiring principles and synthetic models.

The first group includes four chapters: (1) ► [“Brain Atlases,”](#) a collection of pointers to other chapters that describe in detail available brain atlases; (2) ► [“Connectome, *Drosophila*,”](#) a chapter with a detailed survey of the known partial connectomes of the *Drosophila*, with perspectives on the utility, progress, and future of *Drosophila* connectome research; (3) ► [“Connectome, Mouse,”](#) with a survey of publicly available mouse connectome data; and (4) ► [“Connectome, General,”](#) a general survey of connectomics, its potentials, and its challenges.

The second group includes imaging related chapters: (1) ► [“Imaging, Electron Microscopy”](#) discusses the use of electron microscopy for computational neuroanatomy, and (2) ► [“Imaging, Specimen Preparation”](#) presents methods for brain specimen preparation for subsequent sectioning and imaging. (There are other imaging modalities that are relevant to computational neuroanatomy such as ► [“Physical Sectioning Microscopy”](#) and others discussed in the Brain Imaging section.)

The third group of chapters includes reconstruction algorithms for the extraction of geometrical information from the raw image volumes: (1) ► [“Reconstruction, Electron Microscopy”](#) discusses reconstruction techniques for densely packed neurons in electron microscopy image stacks; and (2) ► [“Reconstruction, Techniques and Validation”](#) talks about general reconstruction methods and validation techniques.

Finally, the fourth group of chapters consists of theoretical insights and computational simulation methods that analyze and utilize the quantified neuroanatomical data: (1) [Networks/Networks](#) discusses various methods for automated

generation of realistic neurons and neuronal circuits for use in computer simulations (also see ► [“NeuroMorpho.org”](#)); and (2) ► [“Wiring Principles, Optimization”](#) presents optimization principles that could potentially be underlying neuronal morphology and connectivity patterns found in the brain.

Other Related Chapters and Resources

There are several chapters beyond this section (and sometimes whole sections) in this encyclopedia that are directly relevant to computational neuroanatomy: (1) Brain Imaging (► [“Connectivity Analysis in Normal and Pathological Brains,”](#) ► [“Multiscale Brain Connectivity”](#)), (2) Brain Scale Networks (► [“Network Theory in Neuroscience,”](#) ► [“Neuropathologies and Networks”](#)), (3) Databases in Computational Neuroscience (► [“NeuroMorpho.org”](#) and many other chapters in this section are relevant), and (4) Model Reproducibility (► [“NeuroML”](#)).

Also see the following edited books and monographs on computational neuroanatomy: (Ascoli 2002; Capowski 2012; Chung 2013).

Notable omissions at the moment include (1) dendritic spine morphology and statistics (Bourne and Harris 2008), (2) delay (axonal conduction delay and integration time) and delay statistics (Lamme and Roelfsema 2000; Nowak and Bullier 1997), and (3) how to utilize gene expression data combined with structural information to infer function (Toledo-Rodriguez et al. 2004).

Conclusion

Computational neuroanatomy provides the foundational framework for building, quantifying, and visualizing comprehensive models of large neurological tissues. These models form the foundation for understanding neural computation by providing the ability to validate hypotheses in silico as well as compare networks for the study of aging and neurodegenerative diseases. Computational neuroanatomy also forms the backbone of connectomics (Sporns et al. 2005), enabling the eventual understanding, replication, and repair of neurological tissues.

Cortex: Overview

Lars Schwabe

Department of Computer Science and Electrical Engineering, Adaptive and Regenerative Software Systems, Universität Rostock, Rostock, Germany

Detailed Description

Anatomically, the cerebral cortex is the outermost neuronal tissue of the brain, and it is believed to play a key role in sensation, perception, higher cognitive functions, and motor control. It is a layered structure referred to as the gray matter, because it contains largely cell bodies as compared to the white matter containing largely myelinated axons. The evolutionary origin can be traced back to reptiles, but it first appeared as a uniform structure in early mammals. The increase in the size of this layered cortical sheet during evolution is believed to be crucial for the development of human cognition and ultimately human culture during human brain evolution. Even though many entries in this section on “Cortex: Models and Computation” are applicable to the **[hippocampus]** as well, the focus is on the phylogenetically younger six-layered neocortex.

Why is it so interesting and important to investigate the cortex using modeling? If the co-occurrence of the expansion of the neocortex during evolution of the emergence of human cognition and culture is more than a suspicious coincident, then understanding the cortex is essential to understand the human condition. Identifying brain and mind is certainly a too naïve approach, but it is now widely accepted that – whatever the relation between mind and brain is – an understanding of cortex will at least constrain theories of how the mind works. Testable theories and predictive models are needed to complement conceptual modeling and colloquial talk on that matter. Moreover, understanding how the cortex operates may help to diagnose neurological diseases earlier, to develop more efficient treatments,

and to construct **[brain-machine interfaces]**. Models in general, and patient-specific models in particular, will be useful to link measurements of macroscopic brain activity obtained with brain imaging techniques to the underlying causes. This rather practical justification for modeling cortex is becoming even more relevant today as a “deliverable” of computational neuroscience. However, accurate and faithful modeling has to deal with the complexity of the neural circuits and the cellular and synaptic heterogeneity. Multiple large-scale initiatives currently address this by collecting massive amounts of data to facilitate the development of faithful models of the cortex. Here, the role of cortical models is in organizing and summarizing the data, and they could even be integrated into (semi)automatic data-driven modeling pipelines with little intervention of a “modeler.” I argue that modeling cortex is interesting and exciting, because despite massive amounts of available data, the activity of modeling will remain in large parts an art: Finding the right level of abstraction to arrive at insights for the question at hand can hardly be automated.

On the one hand, the neocortex is an umbrella for a set of distinct structures that differ, for example, in terms of their function, connectivity, and cytoarchitecture. On the other hand, Mountcastle (1978) suggested that similarities of these neocortical regions point to a common computational machinery in the sense that each region has the same basic architecture and operates according to the same computational principles. This is also the guiding idea of this section, without accepting it as a truism or dogma. It is indeed conceivable that different regions of the neocortex operate according to fundamentally different principles, or that conventional notions of “computation” are not suited as a metaphor to understand the cortex. The philosophy of science is not conclusive regarding a clear distinction of theory vs. model. However, as a tentative distinction for modeling cortex, we may adopt the short-hand definition that theory provides meaning to models, while models explain data.

Computational principles come close to the notion of a theory. With that reading, the entries assembled in this section cover the whole spectrum between theories and models of cortex.

Robert Legenstein (► [“Recurrent Network Models, Reservoir Computing”](#)) summarizes the state of the art in how artificial recurrent neural networks (RNNs) address demanding learning tasks. RNN researchers can be thought of as being in the luxurious position to investigate computations in cortex-inspired architectures without the burden to comply with all the constraints set by experimental neuroscience. The performance of these architectures and learning algorithms can serve as a yardstick for existing biologically more faithful models and as a guideline for constructing new models. Jochen Triesch’s contribution on ► [“Cortical Function, Normative Models of”](#) gives a bird’s eye perspective on how to derive models from computational principles. Cortical modeling involves determining model structure and parameterization, and for data-driven approaches, computational neuroscience has developed a **[rich repertoire of methods]**. The normative approach endorsed by Triesch is a complementary addition for doing this, which applies in particular to explaining cortical networks in terms of their genesis via **[learning mechanisms]**. The contributions of Sophie Deneve (► [“Bayesian Inference with Spiking Neurons”](#)) and Walter Senn and Jean-Pascal Pfister (► [“Reinforcement Learning in Cortical Networks”](#)) are instances of this normative approach. Deneve shows how Bayesian inference can be carried out by spiking neurons. The Bayesian approach turned out to be very fruitful for understanding computations in the cortex as evident by a whole section in this encyclopedia being dedicated to the **[“Bayesian brain”]**. It should be noted that both Deneve’s and Senn’s and Pfister’s entries explicitly address computation with spiking neurons and thus represent an explicit formal link between computational principles and experimentally testable predictions at the level of individual neurons. Both of these

mutually compatible approaches make explicit a notion of optimality as required within the normative approach: The Bayesian approach is based on a principled way of conducting logical inference under uncertainty, whereas reinforcement learning is based on Bellman optimality, i.e., **[decision making]** in dynamic and often only partially observable environments.

In a similar way, Udo Ernst (► **“Center-Surround Processing, Computational Role of”**) addresses the phenomenon of center-surround processing (CSP) from a computational point of view. Even though CSP has been investigated mainly in the visual system, where it is exemplified, e.g., by the phenomenon of end stopping already described by Hubel and Wiesen (Hubel and Wiesel 1965), it is also a candidate for a canonical cortical computation to be found in various cortical regions. Ernst links CSP to the laws formulated by Gestalt psychologists in the early twentieth century but also to modern normative approaches that utilize the statistics of natural visual scenes in explaining physiological and perceptual phenomena. He points out that CSP has been successfully implemented in **[cortex-inspired artificial vision systems]**, where it improved object detection and recognition of natural scenes. Such real-world tests of cortical models are excellent yardsticks modelers may want to consider in addition to reproducing physiological or perceptual phenomena that are usually observed in rather artificial laboratory settings with less naturalistic stimuli. Michael Spratling (► **“Predictive Coding”**) reviews the concept of predictive coding. This is an instance of a theory (in the sense defined above), but models derived from this theory can predict CSP as a by-product. The distinctive feature of predictive coding is that downstream areas in the hierarchically organized cortex continuously predict activity in areas at a lower level of the hierarchy. Given that downstream areas in sensory cortices integrate signals from neuronal populations with adjacent receptive fields (RFs), the predictions carry not only information about anticipated future inputs but also from the

neighboring RFs as in CSP. Models derived from predictive coding are candidates for a canonical cortical computation. Applications to sensory cortices may be relatively straightforward, but the crucial test for a theory is its predictions when extrapolated beyond the *postdoc* explanations of already known phenomena. Let me point out three selected such extrapolations: First, it has been applied to explain mirror neuron activity as the natural consequence of predictive coding in the hierarchically organized “social brain” (Kilner et al. 2007). Second, it has been applied to interoception from which predictions about bodily self-consciousness could be derived (Seth et al. 2011). Third, it has been suggested that it may also be applicable to the **[motor system]** with the surprising consequence that the actual motor acts are carried out to fulfill predictions about sensory consequences of just these acts (Hawkins and Blakeslee 2004) as compared to being only the output stage of a sensory-to-motor transformation. Future experimental studies will need to further test these predictions. Interestingly, Spratling has shown that predictive coding and the concept of biased competition can be thought of as being just variants of the same mathematical model. Thus, while the interpretation of models derived from the predictive coding theory in terms of “prediction of inputs” may be unusual in some cases, as in the case of the motor system, the theory is still a rich framework to systematically derive mathematical models and testable predictions.

Computation cannot be considered in isolation. Communication engineers and designers of processors know this too well. Matthias Bethge (► **“Efficient Population Coding”**) considers how much information is communicated by cortical networks. Bethge introduces the psychometric and neurometric functions and highlights that the information contained in the spiking activity of populations of neurons is often enough to predict the behavioral responses of the whole organisms. This is an empirical finding, but computational neuroscience also needs to ask more fundamental questions such as “how

much information can be transmitted?” Only this allows for assessing how close to optimality the cortical circuits are actually operating. To address such questions, he reviews how the concepts of Fisher and Shannon’s mutual information can be applied to quantify the information content of population activity. Combining the approaches that focus on computation introduced so far with these studies of communication and information content could be a very fruitful direction for future studies, in particular when factoring in limitations due to fiber bottlenecks between cortical areas and energy expenditure.

RNNs are Turing-complete, which means that finite RNNs could, in principle, approximate any computation. However, to determine the computations actually performed by the cerebral networks, it is imperative to develop mechanistically plausible models that explicitly respect the anatomical and physiological constraints set by experimental neuroscience. Sean Hill (► [“Cortical Columns, Models of”](#)) presents models of the so-called cortical column, which itself is a theoretical concept motivated by early experimental studies that showed smooth variation of functional properties tangential to the cortical surface but an invariance across cortical layers at a given position. The notion of a cortical column remains controversial, but for computational neuroscience it is certainly a goal to deliver predictive mechanistic models of signal propagation across cortical layers within an area. Probably the most prominent example of mechanistic network modeling to explain a physiologically observed phenomenon is the models for orientation tuning in primary visual cortex (V1), which are reviewed by Nicholas Priebe and Benjamin Scholl (► [“Emergence of Orientation Selectivity in the Cerebral Cortex, Modeling”](#)). Hubel and Wiesel discovered orientation tuning (Hubel and Wiesel 1959) and formulated a first model, namely, that the tuning derives from the pattern of afferent connections from the thalamus onto neurons in V1. The subsequently developed models emphasized the role of intracortical connections to account for experimentally observed properties of orientation tuning such as contrast

invariance. Interestingly, the original feedforward model by Hubel and Wiesel is still a guiding idea, even though it had to be refined. This highlights that such more informal and conceptual models remain valuable today, even though computational neuroscience has to show explicitly when and how models fail as reviewed by Priebe and Scholl.

In my first entrie (► [“Center-Surround Processing, Network Models of”](#)), I take a similar approach and address the question of how the CSP in V1, as introduced by Ernst, may be realized by cortical circuits. More specifically, I review network models of CSP that are distinct in terms of the assumed pathways. Early models emphasized the role of long-range connections within an area, but later models came to acknowledge the role of feedback from downstream areas. The cortical operating mode in vivo is characterized by strong recurrent excitation and balanced inhibition that affect how single neurons integrate and propagate signals (reviewed in my second short contribution ► [“Balanced State”](#)). Interestingly, more recent modeling studies investigated the role of short-range local connections in CSP and found that the properties of strongly connected recurrent networks in a balanced state need to be considered in models of CSP. Adaptation is another phenomenon that seems to be omnipresent in the cerebral cortex. Klaus Wimmer (► [“Adaptation in Sensory Cortices, Models of”](#)) reviews models of adaptation and considers both their role in perception and how plausible mechanisms such as short-term synaptic depression mediate them. Since strongly recurrent networks in a balanced state with static synaptic connections may already exhibit counterintuitive phenomena, Wimmer argues for systematic modeling studies of structured networks with adaptation mechanisms as an important approach to understand adaptation in sensory cortices.

Selected examples of higher cognitive functions are attention and working memory. Cortical models of these functions are reviewed by Philipp Schwedhelm and Stefan Treue (► [“Attentional Top-Down Modulation, Models of”](#)) and Gianluigi Mongillo (► [“Working Memory, Models of”](#)). Schwedhelm and Treue review

models of attentional top-down modulation. They highlight how phenomenological models have guided experiments and how those fed back into refining the models. Some of the models assume the mechanism of gain modulation but remain intentionally agnostic regarding the biophysical mechanisms. This exemplifies that cortical modeling with a properly chosen level of description could be integrated closely with experimental investigations. Working memory has also been studied experimentally in great detail, but most early network models of the persistent activity that is characteristic for the physiological correlate of working memory were variants of attractor networks, where a self-sustained “bump” of activity was identified with the content of working memory. Only more recent modeling studies suggested that self-sustained activity may not be restricted to the spiking activity of groups of neurons, because the state of synapses with short-term dynamics can also be considered as an activity variable that could be exploited to store self-sustained activity. The idea that synaptic variables, which are by multiple orders of magnitude more numerous than single cell state variables, may be crucial for cerebral information processing has been around in the computational neuroscience community for a long time. However, explicit formal models need to spell this out and show the potential benefit in, for example, systematic simulation studies even if the models are speculative and experimentally very hard to test as in the case of the synaptic theory of working memory. This also applies for models of attention: Given that after 50 years of the discovery of orientation tuning in V1, there is still no agreement on network models of even such a basal response property, it may not come as a surprise that the mechanisms of attention remain elusive. While, for example, mechanistic models of top-down gain modulation via synchronizing the discharges of inhibitory interneurons may be consistent with the available anatomical, physiological, and biophysical knowledge, recording multiple identified inhibitory interneurons in vivo in attentional demanding tasks remains to be achieved.

Another currently only poorly understood phenomenon is how the so-called resting state of the

brain is generated and maintained. Computational Neuroscience research has already identified the problem of explaining mechanistically the ongoing low-activity state in recurrently connected *local* networks (Brunel et al. 2013) and derived models to explain them as a stable attractor. Joana Cabral and Gustavo Deco (► “Spontaneous Activity, Models of”) review models of the *global* spontaneous activity that exhibits characteristic temporal properties and is found in the so-called default mode network. This activity (and the default mode network) has been studied intensively using functional magnetic resonance imaging (fMRI), but Cabral and Deco correctly point out that a deeper analysis of the network models is still needed to provide insights into the dynamical properties of the resting state.

The entries in this section cover computation and modeling of the cortex using different approaches and models at various levels of abstraction. Certainly, the cortex cannot be considered in isolation but needs to be modeled and understood in concert with other structures, such as the [thalamus] and [basal ganglia]. Will it be possible to understand cortex without modeling the whole brain or even closed sensory-motor loops within an “enactive” approach (Noe 2006) that states that to understand the brain – in our case, only the cortex – one needs to look at more than just the brain? This is indeed an open question that is of special interest for philosophers of science and mind. However, I argue that the cortex considered as a complex and self-assembled adaptive structure will remain a challenge for any kind of modeling conducted by Computational Neuroscientists who are open to empirical findings and brave enough to ignore irrelevant details without throwing out the baby with the bath water. The reward shall be motivating: to gain an insight into how the cortex works. Relevance and irrelevance of details needs to be decided on a case-by-case basis, which also depends on the taste of the modeler (or theoretician). Unfortunately, despite a multitude of models and some promising candidates for theories of cortical function, one needs to attest that we are not yet there: A unified theory of cortical computation with associated models still

needs to be derived *and* thoroughly tested. My own requirement for accepting such a theory is that it will cover at least the topics addressed by the entries in this section.

Definition

Computational neuroscience research often produces models that help explain empirical data and provide predictions about the biological systems that produce the data. Empirical and theoretical researchers can benefit from resources that facilitate model publication and exchange and provide neuroscience data that informs and contains these existing and future models.

Detailed Description

Databases of Computational Models

One category of databases in computational neuroscience is those that focus on computational models. The BioModels Database (Li et al. 2010; Vijayalakshmi et al. 2013) is a general repository of computational models of biological processes that includes some models from neuroscience. The SenseLab database, ► [“ModelDB”](#) (Migliore et al. 2003), provides a resource for published neuroscience models in a variety of formats. Many of these were developed specifically for simulating the electrophysiological and neurochemical properties of single neurons and networks of neurons, for example, with multicompartment Hodgkin-Huxley type

conductance-based models (Hodgkin and Huxley 1952). The Physiome Model Repository (see ► [“Physiome Repository”](#)) (Yu et al. 2011) is a software suite that facilitates storage and management of models, focusing on those described in ► [“CellML,”](#) a standard markup language for biological models. Similarly, ► [“Open Source Brain”](#) (Gleeson et al. 2010b) is a community platform for collaborative development of computational neuron and network models that utilizes open standards such as ► [“NeuroML”](#) (Gleeson et al. 2010a) to facilitate interoperability and visualization of neuroscience models developed by different researchers. Thousands of models at multiple scales (ion channels, neurons, circuits) have been converted to the NeuroML standard, and these can be obtained at NeuroML-DB (Birgiolas et al. 2015), which also reports the results of many standard physiological, morphological, and computational measurements and experiments on these models to better understand how they behave.

Databases of Neuron Morphology and Physiology

A second category of databases that are important for the computational neuroscience community includes those that contain structured information specific to neurons and their properties. For example, information on the detailed shapes of neurons (morphology) is compiled by NeuroMorpho (see ► [“Neuromorpho.org”](#)) (Ascoli et al. 2007) which contains user-submitted neuron morphological reconstructions made, for example, using the NeuroLucida application (Glaser and Glaser 1990). Similarly, other SenseLab databases (see ► [“SenseLab: Integration of Multidisciplinary Neuroscience Data”](#)) including NeuronDB and CellPropDB (Crasto et al. 2007), contain information on the ionic currents and neurotransmitters expressed by each neuron and how these are distributed with respect to neuronal morphology.

Measured electrophysiological properties of neuron types, and the metadata associated with these measurements, are cataloged in the ► [“NeuroElectro Project”](#) (Tripathy et al. 2014). Detailed information on ion channel subtypes, including voltage and temporal dynamics, genetic homology, and corresponding literature

references, is available at Channelpedia (Ranjan et al. 2011, <http://channelpedia.net>), a subproject within the Blue Brain Project (Markram 2006).

Information about neurons in specific brain areas, including many representative examples, are also publicly available. For example, the Neocortical Microcircuit Collaboration Portal contains information about primary somatosensory cortex (citation), The Allen Institute for Brain Science Allen Brain Atlas includes a Cell Types Database that covers primary visual cortex (Sunkin 2013), and ► [“Hippocampome.org”](#) covers hippocampus (Wheeler et al. 2015).

Relevant to these databases that provide data that are helpful for constraining computational models, the performance of models on experimental-data-driven unit tests is reported at SciDash.org, enabling direct model comparison on properties or predictions of interest.

Resources for Brain Connectivity

Another category of databases focuses on the anatomical organization of the brain. Here we provide some widely used examples, focusing on those that could provide quantitative constraints for modeling efforts. ► [“BrainInfo”](#) provides general information about brain areas, including what they do, where they are located, and what they contain. The Allen Institute for Brain Science provides brain-wide gene expression atlases, where the expression of each of the genes in the mammalian genome has been systematically quantified throughout the brain for a number of animal species and across stages of neural development, as well as anatomical connectivity of different brain regions (Lein et al. 2007, <http://brain-map.org>).

Parallel to this effort is the ► [“Human Connectome Project”](#) (Marcus et al. 2013), a large-scale effort to map complete structural and functional neural connections in vivo in individual humans. ► [“BrainMap”](#) (Laird et al. 2004) consists of a database and related software to search published functional and structural human neuroimaging experiments. In contrast, CoCoMac (Stephan et al. 2001; Bakker et al. 2012) is focused on the primate brain, containing records of tracing studies in the macaque. Finally, the ► [“Cell Centered Database”](#) (Martone et al. 2003, 2009) focuses on images

from light and electron microscopy, ranging from whole brain areas to subcellular compartments.

Other Resources

In addition to these neuroscience domain-specific databases are federated databases that provide linking facilities for cross-resource data integration. For example, NeuroLex (Larson and Martone 2013) provides a platform for community annotation of neuron types on the basis of morphological, neurochemical, or electrophysiological properties. Given this wealth of neuroscience resources, the ► “Neuroscience Information Framework (NIF)” provides tools for semantic search across these diverse databases (Gardner et al. 2008) through the development and incorporation of neuroscience domain-specific ontologies (Bug et al. 2008; Larson and Martone 2009; Hamilton et al. 2012; Imam et al. 2012). For example, in NIF, the search query “mitral cell” returns a number of database records including relevant research literature from PubMed, computational models from ModelDB, and connectivity information from BAMS.

The number and size of these databases continue to grow with the collection and contribution of ever more models and data. These databases give computational neuroscientists a powerful tool for constraining data-driven models and serve as an alternative to conventional literature searches.

Decision-Making: Overview

Emilio Salinas

Department of Neurobiology and Anatomy,
Wake Forest School of Medicine, Winston-Salem,
NC, USA

Detailed Description

Much of computational neuroscience begins and ends with the responses of individual neurons. The field itself sprang from work in the 1950s aimed at uncovering the biophysical mechanisms underlying spike generation (Hodgkin and Huxley 1952), and other classic studies focus on the computational capabilities of dendritic trees and on how neural activity encodes sensory stimuli or statistical information about the world, to mention a couple of well-known examples (Dayan and Abbott 2001). A different point of view, however, is one in which neurons are the intermediaries between a subject and its environment. As the engines of behavior, neurons need to be computationally powerful for the express purpose of giving the subject an advantage, and hence their efficiency or performance should be measured with respect to the subject's success. So the computational neuroscience of decision-making is computational neuroscience in this context; it is the quest to understand how single-neuron activity contributes to nonreflexive actions, actions that cannot be predicted from a subject's history alone.

The idea of quantitatively explaining a person's subjective experiences based on the responses of specific groups of neurons goes back to the 1960s, with the work of Vernon Mountcastle and colleagues in the somatosensory modality. They found, for instance, that when a small probe, similar to the tip of a ballpoint pen, vibrates at a frequency of 2–40 Hz, the intensity of the evoked sensation reported by a person is directly related to the neural responses of a particular type of mechanosensory receptor under the skin, now known as a Meissner corpuscle (Talbot et al. 1968). Many design elements and analytical

techniques used in contemporary experiments were already laid out in those pioneering studies: they applied information theory to determine the coding capacity of sensory neurons (Werner and Mountcastle 1965) very much as is done today, except for the rudimentary computers, and they recognized neuronal variability, as well as rate versus temporal coding, as fundamental issues for neural computation (Werner and Mountcastle 1963). This early work was limited, however, because it compared psychophysical performance in one system (behaving humans) with neural activity in a different system (e.g., anesthetized monkeys). It was later, with studies like those of William Newsome and colleagues (Salzman et al. 1992), that vision became the more popular modality and that both behavioral and neuronal responses were simultaneously recorded in the same subjects during the performance of perceptually based tasks. That became the standard and a cornerstone for investigating the neural basis of decision-making (Parker and Newsome 1998).

Thus, decision-making involves the study of neurons and neural circuits as a subject captures information about the sensory world; analyzes it; combines it with other stored information about current goals, priorities, and possible courses of action; and makes a response. In the laboratory, researchers attempt to simplify this as much as possible while still maintaining the essence of the process – an internal evaluation that is not fully predictable – and while measuring three quantities as accurately as possible: the sensory stimuli, the relevant neuronal activity, and the subject's behavior (Parker and Newsome 1998). So even the simplest possible decision-making task requires various types of neural computations, and indeed, one common strategy in the field has been to try to break down the problem into temporally discrete steps (e.g., fixation, stimulus presentation, response selection, reward delivery), to investigate how neurons in various areas participate in specific aspects of the decision-making process (Romo and Salinas 2003). The articles that comprise this section of the Springer Encyclopedia of Computational Neuroscience review key components of any such decision-making process.

Three of the entries (► [“Decision-Making Tasks”](#); ► [“Choice Behavior”](#); ► [“Categorical Decisions”](#)) emphasize the repertoire of tasks and associated mathematical models that have been successfully used to characterize and quantify behavior. This provides a foundation for understanding how primary factors, such as reward availability or the quality of sensory information, drive a subject's actions and how different tasks place demands on different cognitive functions, such as perceptual discrimination, conflict resolution, or working memory capacity, to name a few. Selection of a particular behavioral task thus determines both the specific cognitive function and the corresponding neural circuits under investigation. In this context, it has become clear that individual choices are often influenced by a variety of subtle factors that superficially may appear inconsequential (► [“Decision-Making, Bias”](#)). Such sources of bias are likely to attract increasingly more attention in the future, as our ability to correlate neuronal activity and behavior becomes more sophisticated.

Most decision-making tasks have at least two components: a perceptual step during which current sensory information is analyzed (e.g., is that spot red or green?) and a motor report whereby the result of the perceptual judgment is indicated (e.g., push a left or a right button). The rest of the articles in the section focus either on perception (► [“Accumulation of Evidence in Decision-Making”](#)), motor planning (► [“Decision-Making, Motor Planning”](#)), or their interface and interaction. Although some neurons clearly relate to either perceptual or motor processing, it is often the case that the cells that correlate most strongly with a subject's choices have elements of both (► [“Perceptual Decision-Making”](#)). In fact, determining the degree to which a neural response encodes perceptual information versus a motor plan turns out to be surprisingly difficult (► [“Target Selection vs. Response Selection”](#)); the ambiguity arises even at the psychophysical level (► [“Perceptual-Motor Dissociation”](#)). In spite of this, a number of principles describing how neurons participate in the generation of perceptual judgments and ultimately produce choices have been identified (► [“Perceptual Decision-](#)

Making”). Furthermore, relatively simple quantitative models have been highly successful at reproducing not only the traditional behavioral metrics of performance and reaction time but also key aspects of neuronal activity (► [“Accumulation of Evidence in Decision-Making”](#); ► [“Decision-Making, Models”](#)). Because of this, there is a relatively thorough understanding of at least some of the computations that are key to perceptual decision-making (► [“Accumulation of Evidence in Decision-Making”](#); ► [“Speed-Accuracy Tradeoff”](#); ► [“Decision-Making, Threshold”](#)). This trend is expected to continue.

Deep Brain Stimulation (Models, Theory, Techniques): Overview

Peter Alexander Tass^{1,2} and
Christian Hauptmann³

¹Department of Neurosurgery, Stanford University, Stanford, CA, USA

²Department of Neuromodulation, University of Cologne, Cologne, Germany

³Institute of Neuroscience and Medicine – Neuromodulation (INM–7), Research Center Jülich, Jülich, Germany

Detailed Description

Deep brain stimulation (DBS) of the subthalamic nucleus (STN) is a well-established treatment for medically refractory patients with advanced Parkinson’s disease (PD) (Benabid et al. 1991; Blond et al. 1992; Benabid et al. 2002; Deuschl et al. 2006) as well as for patients with early motor complications (Deuschl et al. 2006; Schuepbach et al. 2013). Several neurological diseases, such as Parkinson’s disease (PD) or essential tremor, are characterized by pathological synchronization (Nini et al. 1995; Brown et al. 2001). Parkinsonian resting tremor, for example, seems to origin from a pacemaker-like population of neurons of the basal ganglia firing in a synchronized and oscillatory manner (Hutchison et al. 1997; Hurtado et al. 1999; Magill et al. 2001; Trottenberg et al. 2007). In contrast, under healthy conditions these neurons are active in an uncorrelated and desynchronized manner (Nini et al. 1995; Magill et al. 2001).

The standard DBS protocol employs permanent high-frequency (>100 Hz) pulse train stimulation (Benabid et al. 1991, 2002; Blond et al. 1992). Symptom suppression by DBS is strongly dependent on stimulation frequency – with only high frequencies (>100 Hz) being effective and effects being rapidly reversible (Birdno and Grill 2008). High-frequency DBS was developed empirically, mainly based on clinical observations and experimental results (Volkman et al. 2006), and the mechanism of high-frequency DBS is still a matter of debate (Benabid et al. 2005).

Experimental observations indicate that during high-frequency DBS, a regular bursting mode is induced (Beurrier et al. 2002), and after a reduction of stimulation artifacts, robust bursting activity in STN neurons was observed in slice experiments (Beurrier et al. 2001). In the same experiments, the offset of stimulation was followed by a blockade of activity, i.e., a depolarization blockade (Beurrier et al. 2001). These observations were made in anesthetized animals and are contradicted by measurements in awake behaving primates (Anderson et al. 2003; Hashimoto et al. 2003; Dorval et al. 2008) and rats (McConnell et al. 2012). Other groups argue that high-frequency DBS blocks neuronal activity in relevant target areas during stimulation and therefore mimics the effect of tissue lesioning (Benabid et al. 2002). In 2005, Benabid and coworkers summarized different hypothetical mechanisms: membrane inhibition, excitation of excitatory and inhibitory afferents, jamming, excitation of efferents, and plasticity (Benabid et al. 2005). Novel experimental techniques, such as optogenetics, enabled to further reveal the mechanism of DBS and, in particular, of the stimulation of afferent axons projecting to the target region (Gradinaru et al. 2009).

Spatially extended single- and multi-compartment neuron models were used to evaluate the contribution of these different mechanisms (Grill and McIntyre 2001; Terman et al. 2002; Rubin and Terman 2004). For example, Grill and McIntyre (2001) showed that depending on the stimulation amplitude and the shape of the stimulation pulses, cells were either activated directly or fibers mediating excitatory or strong inhibitory

action were activated. The activation of a larger number of structures takes place on the single-neuron level with different and possibly conflicting impacts on single-neuron dynamics (Grill and McIntyre 2001). For example, in the same neuron, the cell body (soma) is inhibited as a result of activation of presynaptic axons and GABA release, while the efferent axon is activated by the stimulation pulses on an approximately one for one basis (McIntyre et al. 2004). The various reactions of neurons toward stimulation on the network level further add complexity that is important for the creation of a sound model: cells responding differently to external inputs, such as somatosensory stimulation or stimulation owing to active movements, are present in the target tissue together with so-called no-response cells (Lenz et al. 1994). Therefore, high-frequency stimulation has a complex impact on these structures (Benabid et al. 2002; Shen et al. 2003). However, surprisingly, even single STN model neurons – lacking synaptic dynamics, neural circuitry, and contributions of glial cells – subjected to high-frequency stimulation reproduce clinically observed response characteristics (Pyragas et al. 2013).

To study another aspect of DBS, several groups use physical models based on Maxwell's equations to investigate the neuronal activation profile depending on electrode geometry and stimulation parameters (Butson and McIntyre 2005, 2006; Miocinovic et al. 2009; Yousif et al. 2008; Chaturvedi et al. 2010; Buhlmann et al. 2011).

While the standard DBS protocol was developed empirically (Volkman et al. 2006), novel stimulation approaches are based on electrophysiological as well as computational concepts. Personalizing and optimizing high-frequency stimulation in real time by demand-controlled, adaptive DBS might constitute a superior high-frequency stimulation mode, as shown in an acute study in externalized patients (Little et al. 2013). In addition, modeling studies are used to further develop the stimulation algorithm, beyond standard high-frequency DBS, in order to finally establish superior stimulation mechanisms. For example, coordinated reset (CR), a patterned

stimulation protocol specifically targeting the reduction of synchronized activity, was developed by means of mathematical models (Tass 2003) and essentially aims at an unlearning of both abnormal synaptic connectivity and synchrony (Tass and Majtanik 2006). CR was successfully tested in a preclinical study, where 5 days of low-dose CR stimulation induced long-lasting therapeutic effects for 30 days (Tass et al. 2012). Another example is a closed-loop approach, which was controlled by the extent of oscillatory beta-band activity. During stimulus delivery, this approach resulted in a better reduction of akinesia as well as pallidal firing rates as compared to classical DBS in parkinsonian nonhuman MPTP-treated primates (Rosin et al. 2011). Finally, modifications of the standard HF protocol might offer a novel approach to improve the efficacy of deep brain stimulation (Brocker et al. 2013; Hess et al. 2013).

The combination of all these modeling and experimental and technological approaches plays a vital role in shaping our understanding and helps to improve the promising therapeutic intervention DBS.

Dynamical Systems: Overview

Alla Borisyuk

Department of Mathematics, University of Utah,
Salt Lake City, UT, USA

Definition

Many models of computational neuroscience are formulated in terms of nonlinear dynamical system (sometimes the dynamical system with noise) and include a large number of parameters. Therefore, it is difficult to analyze dynamics and find correspondence between parameter values and dynamical mode. Mathematical theory of dynamical systems and bifurcations provide a valuable tool for a qualitative study and finding regions in parameter space corresponding to different dynamical modes (e.g., oscillations or bistability). Thus, the dynamical systems (or nonlinear dynamics) approach to analysis of neural systems

has played a central role for computational neuroscience for many years (summarized, e.g., in recent textbooks, Izhikevich (2007) and Ermentrout and Terman (2010)).

Detailed Description

Theory of dynamical systems and bifurcations provides a list of universal scenarios of dynamics changes under parameter variation. For example, one scenario explaining the onset of oscillations is described by Andronov-Hopf bifurcation. In terms of neuroscience, this theory provides insight into the mechanisms underlying different neural response properties and firing patterns. Even more importantly, it allowed to elucidate the underlying mathematical structure that might be common to whole classes of firing behaviors. Thus, conclusions of such studies can be wide ranging, even if specific biophysical details of implementation may differ from case to case.

A common theme in all articles in this section is that they use concepts from nonlinear dynamics, especially geometrical methods like phase planes and bifurcation diagrams. Many exploit time scale differences to reduce dimensionality by dissecting the dynamics using fast-slow analysis, i.e., to separately understand the behaviors on the different time scales and then patch the behaviors together.

The articles in this section for the most part exploit the idealized model of neuron localized at one point (i.e., electrically compact neuron), focusing on the nonlinearities of spiking dynamics, and using biophysically minimal but biologically plausible description of neural dynamics. An article on ► [“Fitzhugh–Nagumo Model”](#) describes one of the first examples where dynamical systems approach has been applied to analysis of neural dynamics (Fitzhugh 1955). Although “Fitzhugh–Nagumo Model” is not biologically grounded and formulated in terms of the cubic nonlinearity, the model is still considered as one of the prototype models for excitable systems.

An article on ► [“Morris–Lecar Model”](#) describes the rich dynamic repertoire of the two-variable Morris–Lecar model, as its biophysical

parameters are varied. The original detailed analysis of this model (Rinzel and Ermentrout 1998) has laid ground for similar approaches in many different contexts and provided a theoretical justification for influential Hodgkin’s classification of “excitability types” (Hodgkin 1948, described in ► [“Excitability: Types I, II, and III”](#)).

The articles on ► [“Integrate and Fire Models, Deterministic”](#) and ► [“Theta Neuron Model”](#) models target the most idealized end of the modeling spectrum where the spiking activity is represented by simple mathematical models. This approach to modelling of spiking times is fruitful for implementation in the large neural network and when mathematical analysis (in addition to numerical simulations) is desired.

Somewhat more intricate features of single cell dynamics are described in articles on modelling of ► [“Postinhibitory Rebound and Facilitation”](#) and ► [“Spike-Frequency Adaptation”](#) phenomena. Finally, the fast-slow dissection and bifurcation analysis really shine in the description of bursting behavior. The bursting dynamics (of individual cells or of population activity) is dissected into active and silent phases when trajectories are restricted to lower dimensional manifolds, and transitions between these phases correspond to reaching the manifold’s boundary and jumping to a different manifold.

While most of these examples are for single-cell dynamics, the qualitative mathematical study is also applicable to the dynamics of neuronal networks and structures, especially in the mean-field approximations. One such example for network-generated rhythms is presented in the article on ► [“Spike-Frequency Adaptation.”](#)

Of course, the models presented in this section are rather idealized and simplified for mathematical study compared to many other neuronal models that are designed to investigate the biophysical details of action potential generation: interaction of many known ionic currents, or the spatial propagation of activity, etc. Such minimalistic models however are invaluable when the problem or question at hand require only qualitative or semiquantitative characterizations of spiking activity. This is especially important in studies of large networks of interacting cells.

Definition

Computational neuroscience provides insights into the mechanisms that underlie dynamic diseases of the nervous system. Neuro-computationally inspired therapeutic devices that replace functions lost due to disease offer tangible hope to many for a better life.

Detailed Description

The evolution of an illness is one of the clues that a physician uses to arrive at a diagnosis and treatment strategy for diseases that affect the nervous system. Is the onset acute or subacute? the clinical course self-limited, relapsing-remitting, cyclic, chronic progressive? and so on. The impetus for studying disease dynamics comes from the mathematics and physics communities: their long experience has shown that insights into mechanism often derive from examining how dynamics change. Consequently, the time evolution of a disease is modeled using differential equations and disease processes are described in terms of the stability and nature of the model's dynamical behaviors. In 1977, Michael Mackey and Leon Glass associated changes in physiological dynamics from healthy to unhealthy with changes in underlying control parameters (Mackey and Glass 1977). Subsequently, this concept of a *dynamical disease* was extended to that of a *dynamic disease* to account for the possibility that mechanisms other than those associated with changes in parameters may be involved (see entry ► [“Dynamic Diseases of the Brain”](#)).

Computational neuroscience extends dynamical approaches to neurological disease in two ways (Erdi et al. 2017). First, by making it possible to include anatomical, physiological, and molecular details, computational models provide insights into how mechanisms acting at the level of molecules and individual neurons translate into phenomena manifested clinically at the bedside (see entry ► [“Modeling of Disease: Physical and Molecular Level, Overview”](#)). Historically, the two neurological diseases which provided the most insight into cortical function were temporal lobe epilepsy and classical migraine. Indeed the study of the geometry of migraine, drug, and flicker-induced visual fortification patterns (see entries ► [“Stochastic Neural Field Theory,”](#) ► [“Visual Hallucinations and Migraine Auras,”](#) and ► [“Flicker-Induced Phosphenes”](#)) and their propagation (see entry ► [“Migraines and Cortical Spreading Depression”](#)) has provided deep insights into the functional architecture of the visual cortex. Surgical approaches for the

treatment of patients with medically intractable epilepsy provided the impetus to directly record from cortex of awake humans. This, in turn, motivated studies into the ability of large populations of neurons to synchronize and generate seizures (see entry ► [“Neural Population Models and Cortical Field Theory: Overview”](#)). Moreover, computational models are now making it possible to gain insights into diseases ranging from blood pressure control (see entry ► [“Baroreflex Models”](#)) to the nature of cognitive, functional, and psychiatric diseases of the nervous system that up to now have largely remained mysterious (see entry ► [“Computational Psychiatry”](#)).

Second, by having “a disease in a computer model,” it is possible to efficiently evaluate and refine treatment strategies *in silico* before applying them to humans (Jirsa et al. 2017). Computational challenges remain because of the presence of multistability (see entries ► [“Multistability in Seizure Dynamics”](#) and ► [“Multistability: Stopping Events with Single Pulses”](#)) and time delays (see entry ► [“Time-Delayed Neural Networks: Stability and Oscillations”](#)). Indeed time-delayed, multistable dynamical systems have a tendency to generate transient oscillations that can be easily mistaken for limit cycle oscillations thus causing confusion (see entry ► [“Delay-Induced Transient Oscillation \(DITO\) and Metastable Behavior”](#)).

Although the ultimate goal of medicine is cure, one cannot overlook the need to improve the patient’s quality of life when cure cannot be achieved. The electrical properties of neurons make it possible to use electrical stimuli as a treatment modality. Applications range from aborting seizures with electrical stimuli (see entry ► [“Multistability: Stopping Events with Single Pulses”](#)) to improving the quality of movements of patients with Parkinson’s disease with deep brain stimulation (see entries ► [“Parkinson’s Disease: Deep Brain Stimulation”](#), ► [“Computational Models of Deep Brain Stimulation \(DBS\)”](#), and ► [“Deep Brain Stimulation \(Models, Theory, Techniques\): Overview”](#)). Even noisy stimuli can benefit the function of cochlear implants in the hearing impaired or balance control in those with peripheral neuropathies by making it easier for the sensory nervous system to detect weak signals

(see entry ► [“Stochastic Resonance: Balance Control and Cochlear Implants”](#)). In the last few years alone, these ideas have been translated into devices that can be used by patients, e.g., NeuroPace RNS[®] system for patients with epilepsy, Microsoft’s Emma Watch[®] for patients with essential tremor, shoes with vibrating insoles to improve gait and balance in the elderly (Lipsitz et al. 2015).

As insight increases in our understanding of neural encoding, it is becoming possible to replace broken parts with electronic ones that perform the same function. The large number of articles in this encyclopedia point to the current enthusiasm in this therapeutic approach. Applications include restoring vision to the visually impaired (see entry ► [“Retinal/Visual Interfaces \(Models, theory, Techniques\): Overview”](#)), hearing to those who cannot hear (see entry ► [“Peripheral Nerve Interface Applications, Cochlear Implants”](#)), continence to those incontinent (see entry ► [“Methodologies for the Restoration of Bladder and Bowel Functions”](#)), and relief from pain to those who suffer (see entries ► [“Pain Processing Pathway Models”](#) and ► [“Peripheral Nerve Interface Applications, Neuropathic Pain”](#)). Dramatically it has become possible to interface the brain directly with electronic devices and make it possible for a patient to move robotic limbs by thought alone (see entries ► [“Cortical Motor Prosthesis”](#) and ► [“Functional Neuroscience: Cortical Control of Limb Prostheses”](#)). Even direct brain-to-brain interfaces are possible (Rao et al. 2014).

The frontier for dynamic disease is to understand the collective behaviors of the nervous system that emerge over the time scale of years. Can the development of an epileptic focus (epileptogenesis) be halted early so that an individual at risk never experiences a seizure? Can the rate of learning of a complex voluntary skill, such as the golf swing, by a patient with a robotic or stem cell-derived limb prosthesis be sped up to the point that the individual could enjoy the use of these limbs throughout a lifetime? Large, complex physical systems tend to self-organize dissipative structures, namely dynamical entities whose existence is maintained far-from-equilibrium by a

supply of energy. Already dynamical signatures of this self-organization, including power laws, have been observed in the bursting propagating activities of living neural populations (see entry ► [“Neuronal Avalanches”](#)) and the dynamics of human balance control (see entry ► [“Human Balancing Tasks: Power Laws, Intermittency, and Lévy Flights”](#)).

Computational neuroscience provides the tools for understanding how the nervous system learns to exert control thereby bringing to many tangible hope of a better life.

Gamma and Theta Oscillations, Hippocampus: Overview

Frances K. Skinner
Krembil Research Institute, University Health Network, Toronto, ON, Canada
Department of Medicine (Neurology) and Physiology, University of Toronto, Toronto, ON, Canada

Detailed Description

The brain expresses several rhythms that are associated with normal and pathological states. The hippocampus is arguably the most heavily studied

structure in the brain for many reasons including its importance in learning and memory, and it generates several population activities that include theta and gamma rhythms. Many modeling studies have focused on these oscillatory activities, and the entries in this section detail much of this work. To develop and build models of any biological system, an in-depth appreciation of the biological and physiological basis of what is being modeled is required. This is provided in the ► [“Hippocampus, Theta, Gamma, and Cross-Frequency Coupling”](#) entry, where functional and experimental aspects are described, along with data analysis aspects in ► [“Theta-Gamma Cross-Frequency Analyses \(Hippocampus\)”](#). In developing models, the cellular units and how they are connected need to be examined. Three entries on ► [“Hippocampus, Model Inhibitory Cells,”](#) ► [“Hippocampus, Model Excitatory Cells,”](#) and ► [“Hippocampus, Model Network Architecture”](#) provide these details, and the challenges and complexities in these aspects are laid bare. Three theoretical entries on ► [“Subthreshold Antiresonance and Antiphasonance in Single Neurons: 3D Models,”](#) ► [“Quadratization: From Conductance-Based Models to Caricature Models with Parabolic Nonlinearities,”](#) and ► [“Mixed-Mode Oscillations in Single Neurons”](#) provide the reader with the types of theoretical approaches that can be used to help understand how these subthreshold and mixed-mode activities that are present in hippocampal cells may contribute to theta and gamma rhythms. Gamma rhythms have been extensively studied both theoretically and experimentally, and as such, there are well-developed mechanistic understandings for their generation. These mechanisms are described and illustrated in the entry ► [“Hippocampal Oscillations, Mechanisms \(PING, ING, Sparse\)”](#). This is not the case for theta rhythms or nested theta/gamma rhythms. However, network models have been developed and these are described along with the many considerations that arise in developing such network models in ► [“Hippocampal Theta, Gamma, and Theta/Gamma Network Models.”](#)

In combination, the entries in this section provide the reader with a solid basis to learn about

theta and gamma oscillations in hippocampus considering mathematical modeling and experimental perspectives. An appreciation of the many aspects that are involved, both general and specific, can be gained from reading these entries.

VSCT	Ventral spinocerebellar tract

Definition

Organization of the mammalian spinal cord and activity-dependent and injury-induced plasticity of spinal pathways.

Detailed Description

Somatic perceptions, coordinated movements, and autonomic functions depend on the integrity of the spinal cord and its projections. In Part I of this entry, we describe the classic organization of the human spinal cord which is similar in most respects, except size, to other vertebrate spinal cords (see Sengul et al. 2012; Watson et al. 2010). The organization of the cord determines the accessibility of the neural structures for delivery of stimulation aimed at reengaging or modulating spinal neuronal output. In Part II, consideration is given to how spinal pathways may be modified by activity, injury, and injury followed by activity/stimulation, which is increasingly important in the development and application of rehabilitation protocols. Both type of activity and severity of injury are important in determining the optimal protocols for rehabilitation of individuals with spinal cord injury.

The Spinal Cord Is Organized Segmentally

The human spinal cord is comprised of 31 continuous spinal segments (Fig. 1). These are divided into cervical (C1 through C8) segments that supply the neck and arms, thoracic (T1 through T12) segments innervating the trunk and sympathetic

ganglia, lumbar (L1 through L5) segments supplying the legs, and sacral (S1 through S5) and coccygeal (one segment) segments, supplying the saddle region, buttocks, pelvic organs, and parasympathetic ganglia. Dorsal and ventral roots enter and leave the vertebral column through intervertebral foramina at vertebral segments corresponding to the spinal segment. At its caudal end, the cord tapers to form the conus medullaris and the lumbar, sacral, and coccygeal roots extending to their appropriate vertebral levels to form a bundle, the cauda equina (“horse’s tail”).

The spinal cord is divided into cervical, thoracic, lumbar, and sacral segments. Note the exit of the lumbar and sacral roots through intervertebral foramina located caudal to the spinal segment with which the roots are associated.

General Overview of Spinal Anatomy and Physiology Organization, Fig. 1 Organization of the spinal cord

A segment is defined by dorsal roots that enter the cord carrying sensory information and ventral roots that exit the cord carrying motor commands (Fig. 2). The axons in the dorsal roots arise from dorsal root ganglion (DRG) cells located in paired ganglia lateral to the vertebral column. The axon from each DRG cell bifurcates to give rise to a centrally directed process (dorsal root axon or primary afferent) which projects into the spinal cord to terminate on neurons within the CNS. The peripherally directed axonal process enters a spinal nerve. Some of these peripheral sensory axons transmit information from sensory receptors in the skin; the strip of skin supplied by the peripheral process from cells in one dorsal root ganglion is known as a dermatome (Fig. 3). Other peripherally directed axons innervate the muscle spindles, sensory organs within muscles that mediate proprioception.

In this diagram of two segments of spinal cord, three dorsal roots enter the dorsal lateral surface of the cord, and three ventral roots exit. The dorsal root ganglion contains dorsal root ganglion cells whose axons bifurcate; one process enters the spinal cord through the dorsal root and the other extends peripherally to supply the skin and muscle of the body. The ventral root is formed by axons from motor neurons located in the spinal cord.

Axons from motor neurons in the spinal cord exit in the ventral roots and innervate skeletal muscles or autonomic ganglia. These ventral

root axons join with the peripheral processes of the DRG cells to form spinal nerves, which contain both sensory and motor axons. Several spinal nerves may join to form a peripheral nerve.

Spinal Neurons Are Organized into Nuclei and Laminae

In cross sections, the spinal cord is composed of a butterfly-shaped core of gray matter, containing neuronal and glial cell bodies and their processes that is surrounded by white matter, composed of axons and their associated glial cells. The gray matter is subdivided into a sensory portion, the dorsal (or posterior) horn, and a motor portion, the ventral (or anterior) horn, separated by the intermediate zone (Fig. 4, Table 1).

Comparison of the classification schemes for the neurons in the gray matter of the spinal cord. On the right, a section stained to show cell size, distribution, and location of neurons in the lumbar spinal cord and, on the left, the related laminar boundaries.

The neurons in the spinal gray matter are also classified according to their projections. These include sensory relay neurons, which receive dorsal root input and whose axons project into ascending pathways that terminate in the brain or spinal cord, motor neurons whose axons exit in the ventral roots to synapse on muscle fibers or on neurons in autonomic ganglia, and propriospinal neurons, spinal interneurons whose cell bodies

Physiology
Organization,**

Fig. 3 Dermatome.

A dermatome is the area of skin supplied by axons from a single dorsal root ganglion

and axons are confined to the spinal cord. Proprioceptive neurons are by far the most numerous, accounting for about 90% of all spinal neurons, and the most poorly understood.

Many of the neurons in the gray matter are clustered in functionally related nuclei. These nuclei may extend much of the length of the spinal cord, forming columns of cells, e.g., Clarke's

General Overview of Spinal Anatomy and Physiology Organization, Fig. 4 Organization of the spinal gray matter

General Overview of Spinal Anatomy and Physiology Organization, Table 1 Classification of spinal neurons

Gray matter subdivision	Lamina	Nuclei included in laminae
Dorsal horn	Lamina I	Marginal nucleus
	Lamina II	Substantia gelatinosa
	Lamina III, IV	Nucleus proprius
	Lamina V	Reticular nucleus
Intermediate zone	Lamina VI	Commissural nuclei
	Lamina VII	Clarke's, intermediolateral
		Nuclei
Ventral horn	Lamina VIII	Medial motor nuclei
	Lamina IX	Lateral motor nuclei
Commissure	Lamina X	Central gray

nucleus, the intermediolateral nucleus, and motor neurons. In cross sections, the neurons in the gray matter can also be seen to be distributed in a laminar arrangement, particularly in the dorsal horn. Because the histologic differences among laminae reflect functional differences, the spinal gray matter is sometimes also classified into laminae.

The dorsal horn and intermediate zones (laminae I through VII) contain sensory relay nuclei and include the marginal nucleus (lamina I), the substantia gelatinosa (lamina II), and the nucleus proprius (laminae III, IV). Motor neurons are subdivided functionally into somatic and visceral motor neurons. Somatic motor neurons are located in the ventral horn (laminae VIII and IX) at

General Overview of Spinal Anatomy and Physiology Organization, Fig. 5 External landmarks of the spinal cord

all spinal levels and innervate striated muscle. All visceral motor neurons are located in the intermediate zone (lamina VII) at C8 through L3 (sympathetic) or S2 through S4 (parasympathetic) and innervate neurons in autonomic ganglia. Commissural neurons whose axons cross to the contralateral side of the spinal cord are located primarily in lamina X. These schemes for classifying spinal neurons are compared in Fig. 4 and Table 1.

Ascending and Descending Tracts in the White Matter

The white matter is subdivided into three funiculi: dorsal (ascending pathways), lateral (ascending and descending pathways), and ventral (descending pathways), demarcated by the dorsal median sulcus, the dorsal root entry zone, the ventral roots, and the ventromedian sulcus (Fig. 5). Propriospinal axons ascend and descend in the fasciculus proprius bordering the gray matter. Short propriospinal axons are located medially, immediately adjacent to the gray matter, and longer propriospinal axons ascend and descend, adjacent to the shorter axons.

Cross section of cervical spinal cord shows major landmarks and divisions of white matter.

Cells in the dorsal root ganglia and spinal gray matter give rise to the axons that form the ascending pathways that transmit sensory information to the brain. Cell bodies whose axons course in descending tracts are located in many parts of the brain. Their axons descend in the lateral and ventral funiculi and terminate on motor neurons or, more often, on propriospinal neurons that

project to premotor or motor neurons within the spinal gray matter. Descending systems provide central control of movement and posture. Some descending axons terminate on sensory relay neurons in the dorsal horn and can therefore modify sensory input to the brain. Propriospinal axons may be very short, connecting one cell with its neighbor, others (commissural fibers) cross the midline dorsal or ventral to the central canal, and long propriospinal axons ascend or descend in the white matter to connect distant segments of the cord (e.g., segments supplying upper and lower limbs).

Sensory Pathways

The sensory input to the CNS from the body is organized according to information about the type of sensation (modality) and location of the stimulus. This information is used to produce appropriate spinal reflexes and is transmitted to appropriate parts of the brain for sensory processing. Information about a noxious stimulus to the skin is distributed in pathways that are different from those that transmit information about non-painful stimuli, such as light pressure or proprioception.

Upon entry into the spinal cord, the dorsal root fibers separate into a lateral and a medial division. The lateral division (Lissauer's tract) contains finer myelinated and unmyelinated fibers, originating from small dorsal root ganglion cells, and transmits responses to nociceptive (painful), non-discriminatory or crude touch and thermal stimulation of the skin and viscera. The medial division contains large-caliber fibers from large dorsal root ganglion cells, whose peripheral receptors lie in muscle, joints, and skin. These fibers relay information about muscle length and tension to motor neurons and to propriospinal neurons, at segmental levels and to Clarke's and the lateral cuneate nuclei more rostrally. These pathways provide respectively the basis for spinal reflexes and information about somesthesia and joint position relayed to the brain, providing the basis for stereognosis (i.e., identification of shape and size of an object).

The Lateral Division

Lissauer's tract (Fig. 6) contains small-diameter axons that convey the modalities of pain,

General Overview of Spinal Anatomy and Physiology Organization, Fig. 6 Lissauer's tract

temperature, and crude or nondiscriminatory touch. Some axons branch and the branches ascend or descend in Lissauer's tract for several segments before entering into the lateral portion of the dorsal horn to synapse on cells in the dorsal horn (marginal nucleus, substantia gelatinosa, nucleus proprius, laminae I to IV). This distribution of collaterals rostrally and caudally means that activation of axons in one segment of the lateral division may stimulate dorsal horn cells over several adjacent segments. Neurons in the dorsal horn relay sensory information received from dorsal root axons to nuclei in the brain. These second-order neurons transmit this information through axons that cross and ascend in the lateral funiculus. Sensory relay neurons also receive input from various descending tracts, either directly or via interneurons. In this way, the neuron's ability to respond to sensory input is modified by the brain.

Entry and central course of axons of the lateral division from one dorsal root ganglion. These unmyelinated and thinly myelinated axons may branch and ascend or descend several segments in the tract of Lissauer before entering the gray matter and synapsing on second-order neurons in the dorsal horn.

The formation of the spinothalamic tract (STT) is shown in Fig. 7. Most axons in the STT arise from the marginal cells in lamina I and from the nucleus proprius in laminae III and IV and transmit nociceptive and thermal information. The axons of these second-order neurons cross to the contralateral spinal cord through the ventral

General Overview of Spinal Anatomy and Physiology Organization, Fig. 7 Formation of the spinothalamic tract (STT)

commissure and ascend in the white matter as the spinothalamic tract to terminate in the thalamus and other targets in the brain. They travel with other sensory spino-brainstem pathways in the anterolateral system (ALS).

Lateral division axons entering the dorsal root synapse on second-order neurons giving rise to axons that cross the spinal cord. Some axons form the spinothalamic tract (STT) and ascend to terminate in the thalamus. Some of these axons ascend to terminate in the reticular formation (spinoreticular tract, SRT) or mesencephalon (spinomesencephalic tract, SMT). These pathways travel together in the ventrolateral white matter to form the anterolateral system (ALS).

The Medial Division

Dorsal root axons in the medial division have local targets at their segments of entry. They may also give off collateral axonal branches that ascend to terminate in more distant targets in somatosensory relay and cerebellar relay nuclei.

General Overview of Spinal Anatomy and Physiology Organization, Fig. 8 Medial division

Axons with local segmental targets enter the gray matter, synapse on propriospinal or motor neurons at that segmental level, and subserve reflex organization (Fig. 8). The Ia fibers of the medial division whose peripheral processes innervate stretch receptors in muscle spindles send central processes into the ventral horn, to synapse on the dendrites of motor neurons and propriospinal neurons. The monosynaptic connection between sensory axons and motor neurons is the anatomical basis for an important reflex, the stretch reflex. Other medial division axons, including collaterals of axons with segmental targets, enter the white matter in the dorsal funiculus, where they ascend to terminate in relay nuclei for somatosensory or cerebellar pathways. These relay nuclei receive sensory information from the skin, muscles, joints, fascia, and other tissues and then transmit the information to nuclei in the thalamus. The thalamus relays information to the cortex, where it is consciously appreciated or to the cerebellum, where it contributes to the control of posture and movement, without being consciously perceived.

Axons forming the medial division enter the spinal cord and ascend in the dorsal columns or make local reflex connections on motoneurons or propriospinal neurons or contact spinocerebellar nuclei.

Dorsal root fibers that project to somatosensory relay nuclei enter the dorsal funiculus at each segment, displacing medially the fibers originating from more caudal ganglia. As a result, these fibers become laminated, i.e., topographically

General Overview of Spinal Anatomy and Physiology Organization, Fig. 9 Dorsal column system

organized. In the cervical region, fibers from sacral dorsal roots are found nearest the midline and those from cervical roots nearest the dorsal root entry zone. Fibers representing the lower half of the body (sacral to T5) ascend in the gracile fasciculus; those from the upper half (T5 to C2) comprise the cuneate fasciculus. Axons in both bundles terminate ipsilaterally in nuclei of the medulla for which they are named, the nucleus gracilis and cuneatus. The gracilis and cuneate nuclei (dorsal column nuclei) then relay information to the thalamus (Fig. 9).

Axons mediating fine tactile sensibility contribute to the medial division. They ascend in the dorsal columns to the brainstem, where they terminate on second-order neurons in the dorsal column nuclei. The axons arising from lumbar and low thoracic dorsal root ganglia ascend in the fasciculus gracilis and terminate in the nucleus gracilis. Axons arising from upper thoracic and cervical ganglia ascend in the more laterally located fasciculus cuneatus and terminate in the nucleus cuneatus located lateral to the nucleus gracilis in the medulla.

Other dorsal root axons enter the dorsal funiculus to ascend for several segments before terminating in relay nuclei for cerebellar pathways.

General Overview of Spinal Anatomy and Physiology Organization, Fig. 10 Spinocerebellar systems

Axons arising from DRG cells in caudal thoracic, lumbar, and sacral regions ascend in the dorsal columns to terminate in Clarke's nucleus (Fig. 10), located in segments T1 to L2. Those arising from more rostral ganglia ascend in the dorsal columns to terminate in the lateral (also called the external or accessory) cuneate nucleus in the medulla. The dorsal spinocerebellar tract (DSCT) arises from neurons located in Clarke's nucleus; it ascends in the white matter ipsilaterally and is therefore uncrossed. The DSCT terminates in the cerebellum. Similarly, the cuneocerebellar tract carries information from the lateral cuneate nucleus to the cerebellum. Both nuclei therefore

relay sensory information from the periphery to the cerebellum. There is a third pathway to the cerebellum, the ventral spinocerebellar tract (VSCT). Cell bodies whose axons form the VSCT are distributed throughout the dorsal horn and intermediate zone; their axons cross in the ventral commissure to ascend in the contralateral VSCT, as part of the ALS, to the cerebellum, where they cross again before terminating. Although the course of the VSCT differs from that of the DSCT and cuneocerebellar pathways, their functions appear to be related.

Axons conveying proprioceptive and muscle information also form part of the medial division. Axons from lumbar and caudal thoracic dorsal root ganglia enter the spinal cord and ascend ipsilaterally in the dorsal columns to the thoracic level where they terminate on second-order neurons in Clarke's nucleus. The axons of Clarke's neurons ascend in the lateral funiculus as the dorsal spinocerebellar tract (DSCT) which terminates on third-order neurons in the cerebellum. Axons from more rostral segments ascend synapse in the lateral cuneate nucleus (not shown), which then projects to third-order neurons in the cerebellum.

Motor Pathways

Descending tracts are located in the lateral and ventral funiculi. Most of the axons in these tracts

terminate on propriospinal neurons, which then project to premotor or motor neurons; very few terminate directly on motor neurons. The location of four important descending tracts, the corticospinal, rubrospinal, reticulospinal, and vestibulospinal tracts, is shown in Fig. 11.

The corticospinal tract (CST) descends to the spino-medullary junction, where 90% of the axons cross, and then continues to descend as the lateral corticospinal tract in the lateral funiculus contralateral to the cell bodies of origin. Those axons that do not cross at the spino-medullary junction descend in the spinal cord as the ventral corticospinal tract but then cross in the spinal cord before their termination contralateral to their origin. In rodents, unlike primates and cats, the CST crosses at the spino-medullary but descends in the ventral portion of the dorsal columns within the spinal cord. The rubrospinal tract is also largely crossed and is located in the lateral funiculus. The reticulospinal tract, including the modulatory monoaminergic pathways (serotonergic and noradrenergic), contains axons that arise from reticular nuclei ipsilaterally and contralaterally. The vestibulospinal tract is almost entirely uncrossed.

Somatic motoneurons are somatotopically organized within the ventral horn (laminae VIII and IX). Their axons exit in the ventral roots and innervate striated muscle. A medial motor nucleus is present in the ventral horn throughout the length

General Overview of Spinal Anatomy and Physiology Organization,

Fig. 11 Location of ascending (*right*) and descending tracts (*left*)

General Overview of Spinal Anatomy and Physiology Organization, Fig. 12 Somatotopic organization of ventral motoneurons

of the cord. These motor neurons innervate axial (trunk) musculature. There are also prominent groups of nuclei located laterally in the ventral horn, which are particularly well developed in the lumbar and cervical segments that supply the limbs. The lateral group of nuclei is subdivided functionally into ventral nuclei, which innervate extensor muscles, and dorsal nuclei, which innervate flexors. Within these two subdivisions, the neurons innervating proximal muscles are located medially and those that supply the distal muscles more laterally (Fig. 12).

Axial musculature is supplied by motor neurons located medially and limb musculature by motor neurons located laterally in the ventral horn. Those innervating extensors are more ventral and flexors more dorsal; neurons innervating proximal muscles are more medial than those innervating distal muscles.

Visceral motoneurons (preganglionic neurons) are located in the intermediate zone. They innervate neurons in autonomic ganglia and the autonomic ganglion cells (postganglionic neurons) innervate visceral organs. Those preganglionic neurons in the intermediolateral nucleus in lamina VII at C8 to L3 send axons to the ganglia in the sympathetic chain, providing central regulation of the sympathetic nervous system. Neurons in the intermediate zone at levels S2 through S4 form the more poorly defined sacral parasympathetic

nucleus. Their axons innervate the sacral parasympathetic ganglia and thus provide central control of the sacral portion of the parasympathetic system that mediates bowel, bladder, and sexual reflexes. Central control of more rostral portions of the parasympathetic system is provided by groups of cranial nerve nuclei.

Propriospinal Systems

A great deal of detailed information is available about DRG cells, motor neurons, and their projections. The cell bodies of both motor neurons and DRG cells can be identified morphologically and by methods that label transmitters, receptors, or other cell-type specific molecules. Axonal projections can be visualized and traced by injecting dyes or viral vectors that are incorporated and transported retrogradely, anterogradely, or in both directions and can identify motor neurons that project to specific muscles and DRG cells, as reviewed in Lanciego and Wouterlood (2011).

Propriospinal neurons, however, make up the vast majority of spinal neurons. Because propriospinal neurons are engaged in complex spinal networks, e.g., the central pattern generator (CPG), and in pain transmission (see entry ► [“Sensory Input to Central Pattern Generators,”](#) this volume), a fuller understanding of their connectivity will be important in appreciating how these complex circuits form, how they function, and how they may be modified by activity or injury.

In the last few years, new technologies have accelerated progress in understanding the connectivity and functions of propriospinal neurons (reviewed in chapters in Ziskind-Conhaim et al. 2010, 2013; Conta and Stelzner 2008). The advent of transsynaptic tracing using pseudorabies virus (PRV) and monosynaptic tracing using a genetically modified replication-deficient rabies virus (RV) has provided more detail about interneuronal pathways (Arber 2012; Stepien et al. 2010; Coulton et al. 2011). RV or PRV labeling can be combined with immunocytochemical or other methods to identify the phenotype of the premotor propriospinal neurons.

Developmental neurobiology and molecular genetics have combined to provide additional

ways of differentiating subpopulations of propriospinal neurons, based on lineage (time of origin, birthdate), and the expression of transcriptional markers that control neuronal differentiation and migration to specific positions in the adult CNS. Genetic deletion or pharmacologic blockade can identify the consequences of loss of function in these propriospinal neurons and suggest their roles during development and as adults in the organization of spinal networks (reviewed in Arber 2012; Grossman et al. 2010; Kiehn 2011). These advances have been particularly fruitful in understanding the connectivity of the central pattern generator (CPG). While the network of propriospinal neurons that comprise the CPG is normally modulated by supraspinal projections and afferent input, it can function in the absence of information from the brain or periphery to produce rhythmic, patterned neural activity or fictive locomotion (Hägglund et al. 2010).

The complexity of the propriospinal neuronal connections is still only incompletely understood. The combination and further development of these and other methods that can detect activity in ensembles of functionally related neuronal network and provide 3-dimensional and live imaging, promises a rapid acceleration of progress in this area (Di Maio et al. 2011; Ertuk and Bradke 2013; Hinckley and Pfaff 2013; Laskowski and Bradke 2013).

Spinal Pathways Are Plastic

While the first part of this entry describes the organization of the spinal cord as if it were static, we know that the spinal cord retains the ability to adapt to changes in its environment (plasticity) even in adults. Significant changes in spinal cord neurons and their environment occur as a result of active or passive exercise or training (activity-dependent plasticity). Changes induced by injury occur in afferent, descending, and propriospinal systems and include sprouting, receptor regulation, and alterations in neuronal properties, in addition to the inflammatory and degenerative responses resulting from the injury. When spinal

cord injury is followed by a program of exercise, the functional and anatomical modifications in spinal organization may be further altered or even reversed sufficiently to support greater recovery of function. Understanding lesion-induced changes and promoting plasticity directed by activity can thus be exploited to improve function.

Activity-Dependent Plasticity

Activity-dependent plasticity refers to functional changes in response to activity related to movement. This may include exercise and specific training protocols (Harkema et al. 2012; Roy et al. 2012) or operant conditioning (Pillai et al. 2008; Wolpaw and Chen 2009; Chen et al. 2011) that modify motor output.

Plasticity Following Spinal Cord Injury (SCI)

An injury may be complete (transection spinalization), or it may spare some pathways and thus be incomplete (contusion, clip compression, hemisection, tractotomy). Contusion or clip-compression injuries are considered to be clinically more relevant, while hemisections or tractotomies are surgical injuries that allow evaluation of specific pathways. The consequences of an incomplete injury will depend on which pathways are spared. Spinal cord injury does not elicit substantial regeneration of axotomized neurons and will result in death of some short projecting propriospinal neurons in the vicinity of the injury (Conta Steencken and Stelzer 2010), structural changes in neurons located more distantly from the injury (Gazula et al. 2004), and apoptosis of oligodendroglia (Beattie et al. 2002). Axons that survive an incomplete injury may show long-lasting changes in transmission (Arvanian et al. 2009; Cote et al. 2012) and deficits (but perhaps not permanent) in conduction properties resulting from demyelination (James et al. 2011).

Incomplete SCI is often followed by some degree of spontaneous motor recovery, due in part to reorganization of spared spinal pathway mediated by sprouting and increased excitability of surviving neurons. While gain of function induced by injury may contribute to recovery, it

may also be maladaptive when it contributes to neuropathic pain (Ferguson et al. 2012; Tan et al. 2012), spasticity (Boulenguez and Vinay 2009; Edgerton and Roy 2010), and autonomic dysreflexia (Hou et al. 2008), disorders which often accompany SCI. Complete injury is likely to show little improvement of function in the absence of therapies and is more likely to be accompanied by maladaptive responses.

Activity-Dependent Plasticity After SCI

The functional benefits of treatment based on either exercise-/activity- or injury-induced changes may be modest by themselves, but they are noninvasive and can supplement traditional physical therapy. Consequently, locomotor training after spinal injury (Harkema et al. 2012) is now a widely used rehabilitative strategy to improve function after SCI in humans. Locomotor function on a treadmill can be recovered after spinal transection in experimental animals if training, combined with body weight support, is provided. The success of this therapy is based in part on the normalization of abnormal measures induced by injury when it is followed by training. This effect may relate to the relevance or predictability of the sensory stimulation (Ferguson et al. 2012). The mechanisms that contribute to training-mediated recovery include levels of neurotrophic factors or other molecules (Cote et al. 2011) or changes in gene expression in spinal neurons (Liu et al. 2012; Keeler et al. 2012) and also include changes in neuronal properties and sprouting where exercise/activity tend to ameliorate some of the effects of injury (Cote et al. 2011).

Summary

The spinal cord is contained within the vertebral canal and access to the cord limited by the vertebrae. The cord is somatotopically organized with sensory information being primarily processed in the dorsal horns and tracts, while motor information is mostly contained within the ventral horn and tracts. The intermediate region between the posterior and anterior halves of the cord contains

the largest number of interneurons and is likely the site of most computation processing although the circuitry is still poorly understood. Targeting the activation to certain portion of the circuitry is complicated by both the proximity of the elements forming the circuit and our lack of understanding of its organization. A greater understanding of the anatomical and computational modifications in the spinal circuitry in normal function will be essential for developing ways of improving rehabilitative strategies after injury.

Information Theory: Overview

Alexander Dimitrov

Department of Mathematics, Washington State University, Vancouver, WA, USA

Definition

Information Theory started with Shannon’s seminal paper “A Mathematical Theory of Communication” (Shannon 1948). Because its importance and flexibility were quickly recognized, there were numerous attempts to apply it to diverse field outside of its original scope. The entries in this section provide an overview of the current state of Information Theory in Neuroscience.

Detailed Description

When discussing a field, it is useful to review the basic concepts and their properties. That has been provided in multiple articles for Information Theory. To assist the reader, the entry ► “[Summary of Information-Theoretic Quantities](#)” provides a brief summary of the main information-theoretic quantities. For a more thorough investigation, we would direct interested readers to the most excellent introduction to Information Theory by Cover and Thomas (2006), now in its second edition.

Very soon after Shannon’s initial publication (1948), a small number of manuscripts provided the foundations for the current use of information theory in neuroscience. MacKay and McCulloch (1952) applied the concept of information to propose limits of the transmission capacity of a nerve cell. This work foreshadowed future work on

what can be termed “Neural Information Flow” – how much information moves through the nervous system, and the constraints that information theory imposes on the capabilities of neural systems for communication, computation and behavior. A second set of manuscripts, by Attneave (1954) and Barlow (1961) discussed information as a constraint on neural system structure and function, proposing that neural structure in sensory systems is matched to statistical structure of the sensory environment, in a way to optimize information transmission. This is the main idea behind the “Structure from Information” line of research that is still very active today. A third thread, “Information Estimates,” started with a forward-looking article (Miller 1955), which pointed out many potential pitfalls of extracting information quantities from observations. Its significance penetrated the mainstream neuroscience research later; once information-theoretic analysis became more widespread, the biases noted by Miller were rediscovered, and corrected.

Subsequent Developments

The theme that arguably has had the widest influence on the neuroscience community is that of “Neural Information Flow”. The initial works of MacKay and McCulloch (1952) showed that neurons are in principle able to relay large quantities of information. That research also started the first major controversy in the field, which still resonates today: the debate about timing versus frequency codes (Stein 1967). A steady stream of articles followed, both discussing these hypothesis and attempting to clarify the type of information relayed by nerve cells (Abeles and Lass 1975; Eagles and Purple 1974; Eckhorn and Pöpel 1974; Harvey 1978; Norwich 1977; Poussart 1971; Stark et al. 1969; Taylor 1975; Walloe 1970). After the initial rise in interest, the application of Information Theory to neuroscience was extended to a few more systems and questions but did not spread too broadly. This was presumably because, despite strong theoretical advances in Information Theory, its applicability was hampered by

difficulty in measuring and interpreting information-theoretic quantities.

The work of de Ruyter van Steveninck and Bialek (1988) started what could be called the modern era of information-theoretic analysis in neuroscience, in which Information Theory is seeing more and more refined applications. Their work advanced the conceptual aspects of the application of information theory to neuroscience and provided an impetus to removing biases in information estimates, discussed in detail in the entry ► [“Estimating Information-Theoretic Quantities.”](#)

Current State

Information Theory found applications in the study of neural processing as a theoretical and practical system for the analysis of communicated signals. A variety of information-theoretic quantities are in use in Neuroscience. The entry ► [“Applications of Information Theory to Analysis of Neural Data”](#) provides a general overview of current applications of Information Theory, as an analysis tool of neural information flow.

The structure of neural activity often introduces challenges that have been of marginal interest to the engineering community. The entry ► [“Metric Space Analysis of Neural Information Flow”](#) exemplifies one such case, metrization. In a metric-space approach to analyzing neural response, the data is reduced from a set of complicated objects, spike trains, to a much simpler object, the matrix of distances between the spike trains. When applied to neural information, this matrix is used to estimate information theory quantities for the corresponding spike train data. The tools developed in that direction combine metric properties of spike trains with their information transmission function.

Several entries discuss specific applications in neuroscience stemming from more recent developments in Information Theory. ► [“Directed Information Flow and Causality in Neural Systems”](#) discusses developments based on the natural ideas of information flow in a causal direction. Surprisingly, this idea has taken quite some time to develop in the communication literature due to

various technical difficulties. The works originate from the ideas of Granger (1969) on causal interactions. The information-theoretic perspective of (Massey 1990; Massey and Massey 2005) removed Granger’s linearity assumptions.

And lastly, applications in neuroscience are also pushing the development of new tools in Information Theory. One of the examples presented here, ► [“Information Measures of Redundancy and Synergy in Neural Activity,”](#) summarizes the progress made in that direction, for which the original definitions provided by Shannon proved inadequate.

In conclusion, Information Theory is thriving in the neuroscience community, and the long efforts are bearing fruit, as diverse research questions are being approached with more elaborate and refined tools. As demonstrated by several recent thematic journal issues (Dimitrov et al. 2011; Milenkovic et al. 2010), Information Theory is firmly integrated in the fabric of neuroscience research, and a progressively wider range of biological research in general, and will continue to play an important role in these disciplines. Conversely, neuroscience is starting to serve as a driver for further research in Information Theory, opening interesting new directions of inquiry.

Invertebrate Pattern Generation: Overview

Farzan Nadim

Federated Department of Biological Sciences,
New Jersey Institute of Technology/Rutgers
University, Newark, NJ, USA

Department of Mathematical Sciences, New
Jersey Institute of Technology, Newark, NJ, USA

Detailed Description

Central pattern generators (CPGs) are networks of neurons in the central nervous system (CNS) that produce patterned activity, usually as coherent oscillations, in the absence of external timing cues. CPGs provide timing input to motor neurons whose discharge dictates movements of muscles that control rhythmic behavior such as respiration or locomotion (Marder and Calabrese 1996). The long-held debate between scientists who believed half a century ago that rhythmic motor activity is generated by reflex chains and those who held the more radical view of centrally generated rhythms was resolved conclusively, in favor of the latter group, by demonstrating that neural networks generating rhythmic motor activity can do so in the isolated nervous system, in the absence of the body and therefore sensory feedback. In the early 1960s, these “fictive” motor patterns were first demonstrated to govern rhythmic activation in two invertebrate model systems: the movement of flight wings in locusts and the beating of swimmerets in crayfish (Wilson 1961; Ikeda and Wiersma 1964). The demonstration of fictive motor activity led to the development of *in vitro* preparations in search of the underlying CPG circuits. Although CPG networks have been

traditionally described in the context of controlling motor activity, a more contemporary viewpoint of CPGs includes networks that subserve brain oscillations connected to sensory, cognitive, and memory tasks (Yuste et al. 2005).

CPGs have historically led systems neuroscience in the understanding of neural circuit interactions, partly because of the ease of identification of neurons and networks whose activity correlates with a rhythmic motor activity. The identification of neural circuits has been more successful in invertebrates where the number of neurons involved in neural processing is lower, sometimes by orders of magnitude, and the ability of identifying synaptic connections among neurons is facilitated by dual recordings. Vertebrate and especially mammalian neural circuit analysis was, until recently, performed with cruder techniques such as lesions, but in the past decade or so, genetic tools and the identification of molecular markers have allowed for more precise circuit analysis in the large networks of vertebrate systems (Han 2012; Arrenberg and Driever 2013). However, neural circuits have been identified only in a few vertebrate model systems and simple behaviors (Issa et al. 2011; Cangiano and Grillner 2005). The knowledge of the neural circuits and the ability to record functionally identified neurons in invertebrates have allowed for the in-depth analysis of the mechanisms underlying circuit dynamics and plasticity (Marder et al. 2005) as well as a rigorous description of the computations performed by the neural circuits (Selverston 2010).

The computational description of pattern-generating circuits evolved in parallel with the in vitro experimental studies of cellular and synaptic mechanisms. The complexities of circuit analysis of invertebrate CPGs have led to numerous modeling studies, some of which have been influential in shaping our conceptual understanding of both single-neuron and network operations. For example, the computational description of bursting oscillations, led by models of invertebrate CPG neurons (Plant and Kim 1976), paved the way for the complete mathematical analysis of bursting mechanisms in neurons and other excitable cells (Rinzel 1987; Rinzel and Lee 1987). This section of the Encyclopedia of

Computational Neuroscience provides an overview of the contributions of invertebrate pattern generators in the context of computational models.

Invertebrate Sensory Systems: Overview

Fabrizio Gabbiani

Department of Neuroscience, Baylor College of Medicine, Houston, TX, USA

Definition

Invertebrate sensory systems specialize in gathering information from the surroundings allowing animals to locomote and behave appropriately given the current environmental conditions.

Detailed Description

Invertebrate neurobiology has long been at the forefront of computational neuroscience, starting with the mathematical model of the biophysical basis of the action potential by Hodgkin and Huxley in the squid giant axon almost 70 years ago (Hodgkin and Huxley 1952). Many invertebrate systems are highly suitable for detailed modeling because of their relatively compact size and the fact that their neurons can often be uniquely identified. This feature allows the formulation of precise descriptions of their behaviors and simplifies the interpretation of experimental results. Yet, as Hodgkin and Huxley's seminal analysis of action potential mechanisms has proved, invertebrate models possess characteristics similar to those of vertebrates, and the computational principles derived from either type of nervous systems have been found universally applicable, even if details of mechanistic implementations differ.

This section of the Encyclopedia focuses on the sensory systems of invertebrates, complementing the section on their motor systems. It presents an overview of computational modeling emphasizing salient topics in the field. While the coverage is far from exhaustive, it is our hope that these entries will provide the reader an overview and an entry point to the rich literature covering the modeling of invertebrate sensory systems and related topics.

Among the different sensory systems, vision has arguably been the most intensely investigated in invertebrates and vertebrates alike. The entry on ► [“Phototransduction Biophysics”](#) summarizes our understanding of the mechanisms by which invertebrate photoreceptors translate light signals into membrane potential changes. Most of the work on this topic has been carried out in flies and particularly the genetically tractable fruit fly, *Drosophila melanogaster*. The biochemical cascade mediating phototransduction has been studied in great detail and has recently led to a better understanding of the implications for neural coding. Another classical topic of insect vision has been the study of the mechanisms underlying directionally selective motion detection. This work originated in beetles and was later pursued in flies, leading to the correlation model of Hassenstein and Reichardt (1956). The neural circuits implementing this model, which is closely related to the motion-energy model of mammalian motion detection (van Santen and Sperling 1985), have long proven tricky to investigate due to difficulties in tracing the anatomical and physiological connections between the neurons that perform the computations of the correlation model.

Progress has been made by combining anatomical, electrophysiological, imaging, and genetic techniques in *Drosophila* that are summarized in the entry on ► [“Visual Motion Detection in *Drosophila*.”](#) Although *Drosophila* has recently helped better understand the circuitry underlying motion detection, a large body of work on the topic was carried out in bigger flies, leading to detailed biophysical models of a class of neurons involved in motion detection. These models are introduced in the entry on ► [“Fly Lobula Plate Tangential Cells \(LPTCs\), Models of.”](#) Local

motion detection is only the first step in processing visual information generated by an animal moving in its environment. Such information, often called “optic flow,” is particularly important for flying animals. The strategies and constraints on the processing of such information are summarized in the two entries on ► [“Optic Flow Processing”](#) and ► [“Visual Processing in Free Flight”](#).

Another function of the visual system of critical importance to animals is predator evasion and collision avoidance. Our understanding of the neural mechanisms of collision avoidance has rapidly progressed over the past decades in a variety of invertebrate model systems, including locusts, crabs, and fruit flies. Similar collision avoidance mechanisms have been documented in vertebrate systems such as goldfish, zebrafish, pigeons, and mice. The entry on ► [“Collision Avoidance Models, Visually Guided”](#) describes our understanding of those systems. Animal navigation and migration relies on an internal representation of the external world allowing orientation over long distances. In insects, particularly in monarch butterflies, ants, and locusts, the detection of polarized patterns of light in the sky provides an internal compass for navigation. The detection and processing of polarized light patterns leads to a sort of “cognitive map” in the central nervous system akin to those studied in the rodent hippocampus. The entry on ► [“Polarization Vision”](#) provides a summary of our understanding of this fascinating and exotic sensory modality.

Olfaction is a prominent and important sense in invertebrates, particularly in insects. The mechanisms of insect olfaction and their close relation to vertebrate olfaction have been investigated intensely, culminating in a detailed understanding in several organisms, including moths, locusts, and fruit flies. Examples of models of olfactory coding are presented in the entry entitled ► [“Insect Olfaction: A Model System for Neural Circuit Modeling”](#). Another primary sense, audition, is used by animals to locate preys or predators and for communication with conspecifics. Because of their small size, invertebrates and insects such as crickets and locusts, which are

among the best-studied auditory model systems, face physical constraints quite different from those applying to vertebrates. Their study has led to a wealth of information on how auditory information is processed, both at the level of the auditory periphery and in the brain. These results are summarized in the entry on ► [“Auditory Processing in Insects”](#).

Wind and air current sensing is carried out by a specialized sensory system called the cercal system in crickets and other orthopteran insects. This system provides a fascinating example of how information is processed by populations of sensory neurons, as summarized in the entry entitled ► [“Cercal System”](#). More broadly, the entry on ► [“Computation with Population Codes”](#) explains the role such neural codes play in a variety of other animals. The leech has proven to be one of the best models to study these topics because of the compact size of its nervous system, well-understood natural behaviors, and the applicability of large-scale imaging of neuronal activity using voltage-sensitive dyes and other electrophysiological techniques. Finally, invertebrate somatosensation is introduced in the entry on ► [“Tactile Sensing in Insects”](#).

Adaptation is a fundamental property of neuronal responses observed throughout sensory systems. The entry entitled ► [“Biophysics of Adaptation in a Computational Model of the Leech T Neuron”](#) details the ionic mechanisms of adaptation in one type of sensory neuron and its consequences for the processing of sensory stimuli.

In addition to the above-mentioned entries, the section includes one entry – entitled ► [“Nitric Oxide Neuromodulation”](#) – on a somewhat exotic and fascinating volume neuromodulator: nitric oxide. The computational properties of nitric oxide neuromodulation have been investigated in detail in several invertebrate systems, leading to models of its role in sensory processing and learning. Similar regulation of neuronal circuits by volume neurotransmission has been described in vertebrates as well (e.g., Oláh et al. 2009).

The last topic covered in this section is the efficient representation of neural information in the entry entitled ► [“Sensory Coding,](#)

Efficiency". The possibility that sensory neural codes may be efficient has been first raised in the 1960s (Barlow 1961). It has since then been investigated in several systems, including the visual system of invertebrates. The entry includes background information and a summary of results on efficient coding in these systems.

Learning Rules: Overview

Klaus Obermayer¹ and Joaquín J. Torres²

¹Neural Information Processing Group, Institute of Software Engineering and Theoretical Computer Science, Technische Universität Berlin, Berlin, Germany

²Institute “Carlos I” for Theoretical and Computational Physics and Department of Electromagnetism and Matter Physics, Facultad de Ciencias, Universidad de Granada, Granada, Spain

Definition

The title of this entry, namely, “Learning Rules,” refers to several type of methods and procedures that have been used in different neuroscience research areas to quantify how previous experiences, training, and stimulations protocols affect brain response and behavior in different animals and at different levels of description. The concept assumes the such previous experiences produce changes or plasticity in the brain (i.e., the learning rule) that affect its posterior behavior, e.g., under the action of related stimuli (the retrieval of what is learned). Such “Learning Rules” concept has been also extended to neural networks modeling and artificial intelligence research, providing precise mathematical definitions for different learning rules, a fact that has helped to gain a better understanding of their consequences.

Detailed Description

Learning is the most important procedure by which different stimuli in the environment alter the behavior in animals and humans, and today its neurobiological base is widely accepted (Thompson 1986). In fact, neurobiological and computational studies have stressed the significance of synaptic plasticity in the learning process (Black et al. 1990; Fusi 2017): Experience and training leads to modifications of synapses, which in turn lead to changes in neuronal firing patterns,

causing changes in behavior. A full understanding of the processes underlying learning, therefore, requires an understanding on the neural as well as on the systemic level.

In the behavioral literature, learning is studied by means of different experimental procedures in which animals or humans are exposed to sensory stimuli and interact with the environment (Mackintosh 1974). The paradigms which have been used gave rise to a categorization into associative and nonassociative learning. In non-associative learning an animal is repeatedly exposed to a single type of stimulus, and learning is described by the strength of its behavioral impact leading, for example, to the phenomena of habituation and sensitization (Thompson and Spencer 1966; Rankin et al. 2009). In associative learning animals learn predictive relationships in the presence of a reinforcement signal (Pearce and Bouton 2001). Historically, classical conditioning (where reinforcements are delivered independent of any action taken) is differentiated from operant conditioning (where reinforcements depend on the action and where behavior is associated with its outcome).

In the neural network literature (see, e.g., Haykin 2009), learning is often classified according to what kind of information is available in a particular learning scenario. In the so-called supervised learning, an agent (e.g., a neural network) forms associations between two sets of events with the goal to predict one by the other. Learning is based on a given set of correct pairings. Pairings between events are also formed in the so-called reinforcement learning; however, evaluative feedback about network performance is only provided in the form of reinforcements, for example, reward or punishment signals. Correct pairings imply high rewards; hence, learning is driven by maximizing returns. Reinforcement learning bears similarities with the abovementioned associative learning paradigms, and algorithms which were originally developed by the neural network community are now widely applied to quantify associative learning in animals and humans. In the so-called unsupervised learning, responses of an agent are modified when stimuli are presented but in a nonassociative way. In an artificial agent setting, supervised learning is often applied for solving pattern recognition problems,

and reinforcement learning is used to learn action sequences. Unsupervised learning, on the other hand, is applied to learn internal representations of the outside world. Statistical regularities are extracted and are used to build representations of stimuli and actions which are better suited for recognition, planning, memorization, decision-making, and other cognitive tasks.

In many areas of neuroscience where “real” neurons and networks are studied, learning is linked to changes of neuronal and synaptic properties. Activity-dependent synaptic plasticity is widely believed to be the most important feature underlying learning. It also plays an important role during neural development, where the interplay of neural activity with the so-called intrinsic processes shapes the circuitry and the neural response properties. Learning at the neuronal level is characterized by how the activation history of pre- and postsynaptic neurons relates to the efficacy of the synaptic connection between them. Different stimulation protocols of neurons in (mostly) *in vitro* preparations uncovered a wealth of phenomena associated to learning processes, the most prominent ones being long-term potentiation, long-term depression, or spike-timing-dependent plasticity.

“Learning Rules,” i.e., the title of this entry, refers to the quantification of the effects of experiences, training, and stimulation on the brain and behavior on all abovementioned levels of description. Learning Rules inserted into computational models then help to explore the consequences of the observed plasticity during different learning processes. Thus, one can explore, for example, how activity-dependent synaptic plasticity interacts with network responses which eventually induce behavior, how a network can adapt its parameters such that a desired function can be performed, or how interindividual differences in learning behavior can be related to interindividual differences in their objectives. Thus, learning rules serve as a computational tool to link experience-induced changes observed on a system level to the mechanisms operating on the level of neurons and networks and vice versa.

At the core of this entry are entries for activity-dependent learning rules, which quantify how pre- and postsynaptic activity changes the strength of a

synapse (see entries ► [“Hebbian Learning,”](#) ► [“Anti-Hebbian Learning,”](#) ► [“Spike-Timing Dependent Plasticity, Learning Rules,”](#) and ► [“Tempotron Learning”](#)). Here, the learning rules are formulated in a more abstract setting, and the biophysical foundations are addressed in entry ► [“Synaptic Dynamics: Overview”](#) (cf. ► [“Long-Term Plasticity, Biophysical Models,”](#) ► [“Short-Term Plasticity, Biophysical Models,”](#) and ► [“Spike-Timing Dependent Plasticity, Learning Rules”](#)). The effects of learning rules in terms of network dynamics and computation are then addressed in a neural network setting (see entries ► [“Boltzmann Machine,”](#) ► [“Hopfield Network,”](#) ► [“Perceptron Learning,”](#) and ► [“Slow Feature Analysis”](#)) covering supervised and unsupervised learning paradigms. They are also addressed in a neural modeling setting, where the computational models are used to understand some of the mechanisms underlying neural development (see entries ► [“Cortical Maps, Activity-Dependent Development”](#) and ► [“Cortical Maps, Intrinsic Processes”](#)). The entry is complemented by one entry on reinforcement learning (see ► [“Reward-Based Learning, Model-Based and Model-Free”](#)), which summarizes current computational approaches for quantifying behavior for reward-based, associative learning paradigms. Possible neural implementations of reinforcement learning are discussed in entry ► [“Cortex: Overview”](#) (cf. ► [“Reinforcement Learning in Cortical Networks”](#)).

Detailed Description

Local field potentials (LFPs) are low-frequency electrical potentials recorded with micro- or

macro-electrodes throughout the brain. The upper frequency cutoff of the LFP is often considered to be around 100 Hz but may be as high as 500 Hz in some studies. The normal amplitude of the LFP can range from a few microvolts (e.g., in the basal ganglia) (Goldberg et al. 2004) to hundreds of microvolts in the cortex. Perhaps the earliest recording of an LFP may be attributed to Renshaw, Forbes, and Morison in 1940, who described these potentials in the cortex and the hippocampus of a cat under various anesthetics (Renshaw et al. 1940). Extensive electrophysiological studies have formed the current view that cortical LFPs result from synaptic activity (Eccles 1951; Creutzfeldt et al. 1966; Elul 1971; Klee and Rall 1977; Mitzdorf 1985; Bedard et al. 2004). Correspondingly, the LFP fluctuations tend to have a strict phase relationship to cortical discharge: negative deflections in the LFP coincide with increases in the instantaneous firing rates of cortical neurons in both superficial and deep layers (Lass 1968; Gray and Singer 1989; Murthy and Fetz 1996a; Donoghue et al. 1998; Destexhe et al. 1999). In addition, these fluctuations are highly correlated across distances of several millimeters in the cortex (Eckhorn and Obermueller 1993; Sanes and Donoghue 1993; Murthy and Fetz 1996b; Contreras et al. 1997; Bullock 1999; Destexhe et al. 1999), indicating that LFPs are not always strictly local.

Theoretical attempts to account for the LFPs and model their generation date back to Lorente de Nó (1947) and include the seminal works of Ulla Mitzdorf (1985), who implemented the technique of current source density (CSD), and Wilfrid Rall, who calculated the potentials generated by various spatial organization of electrical dipoles (Klee and Rall 1977; Goldberg et al. 2004). These theoretical accounts relied on the large-scale repetitive columnar structure of the cortical circuitry to generate large potentials due to the summed contribution of many aligned neuronal dipoles (Elul 1971; Klee and Rall 1977; Abeles 1982; Mitzdorf 1985; Eggermont and Smith 1995).

This “LFP analysis” section, which has contributions from several leading authorities, covers the following topics: (a) methods for measuring

the LFP; (b) modern accounts of how LFPs are generated; (c) the relationship between the LFP and other common measures of collective brain activity such as the EEG, the MEG, and the fMRI, as well as its relationship to and possible influence on single-cell membrane potentials; (d) the power spectral structure of the LFP, which often displays a $1/f$ structure, or marked oscillation peaks under various physiological and pathophysiological conditions (e) LFP in the context of particular brain functions such as vision and olfaction; and (f) current modeling methods of the LFP. These various topics are overviewed below.

Neurophysiological Basis of LFPs

A first important aspect of the LFP is the relation between this signal and other well-known signals of the brain. In the entry ► [“Local Field Potential, Relationship to BOLD Signal”](#), Nikos Logothetis and Stefano Panzeri review the relation between the LFP signals and the BOLD (blood oxygen level dependent) signal, as recorded by MRI techniques. The entry also discusses multiunit activity in relation with the BOLD signal.

A similar large-scale approach is followed by Stephanie Jones in ► [“Local Field Potential, Relationship to Electroencephalogram \(EEG\) and Magnetoencephalogram \(MEG\)”](#). This entry reviews the biophysical bases of the genesis of EEG and MEG signals and how such signals relate to the LFP. The “inverse problem” of estimating neuronal sources from EEG and MEG signals is also reviewed.

The relationship to unit activity is further described in detail in ► [“Local Field Potential, Relationship to Unit Activity”](#) by Bartosz Teleńczuk and Alain Destexhe. This entry reviews the relation between extracellularly recorded unit activity and LFP, as a function of the frequency of the different rhythmical activities found in LFPs. It is shown that unit activity correlates with the high-frequency (>200 Hz) components of the LFP and, to a lesser extent, with the low-frequency components (<10 Hz), whereas the intermediate-frequency bands have a rather weak correlation with unit activity.

In the entry ► [“Local Field Potential: Relationship to Membrane Synaptic Potentials”](#), Aryeh Taub, Ilan Lampl, and Michael Okun go a bit more deeper in the neuron and review the relation between the intracellularly recorded membrane potential and the LFP signal. The entry considers different types of brain activity, such as up-down states, and discusses the role of inhibition.

In the entry “Local Field Potentials and Ephaptic Coupling”, Costas Anastassiou discusses the hypothesis that the LFP is not merely an epiphenomenon of electrical brain activity but may actually serve as a global slow signal that can couple to other neural elements (e.g., axons, synapses). This ephaptic coupling results from the fact that the membrane voltages in these elements can be altered by fluctuations in the LFP simply because they are the difference between the intracellular potential and the extracellular (local field) potential.

Finally, in the entry ► [“Local Field Potentials: LFP”](#), Alain Destexhe and Claude Bedard review general properties of LFPs, such as their spatial coherence, namely, how LFPs recorded by neighboring electrodes relate to each other. They also review temporal (spectral) properties of LFPs, such as their typical $1/f$ structure. The entry also overviews different approaches for modeling LFPs.

Oscillatory Properties of LFPs

A fundamental property of LFP signals is their propensity to display oscillations. In the entry ► [“Local Field Potential and Deep Brain Stimulation \(DBS\)”](#), Manuela Rosa, Sara Marceglia, Sergio Barbieri, and Alberto Priori review the use of LFPs in the treatment of DBS in humans. It describes how DBS provides LFP recordings in humans, how they are related to oscillatory activity, and how DBS may interfere with these (sometimes pathological) oscillations.

Pathological oscillations are further investigated in the entry ► [“Local Field Potential and Movement Disorders”](#) by Annaelle Devergnas and Thomas Wichmann. They review the use of LFP recordings in movement disorders and show

that LFPs display various types of oscillations, at different frequencies, for different pathologies associated to movement disorders.

In the entry ► [“Local Field Potentials in Olfaction”](#), Leslie Kay review the LFP signals recorded in the olfactory system (olfactory bulb and pyriform cortex). Their review emphasizes the emergence of beta and gamma oscillations in olfactory structures.

The occurrence of LFP oscillations in the visual system is investigated in the entry ► [“Local Field Potential in the Visual System”](#) by Gregor Rainer. This entry reviews the occurrence of LFPs in visual cortex, with an emphasis on visually evoked potentials, and visually evoked oscillations in the gamma frequency band.

Finally, in the entry ► [“Local Field Potential, Synchrony of”](#), Ariana Frederick, Jonathan Bourget-Murray, and Richard Courtemanche review how LFPs can reveal the presence of network synchrony. Synchrony is here defined as the synchronization between different networks, which indicates a possible interaction between them, for example, using oscillations at different frequencies.

Modeling the Spectral Structure of LFPs

The modeling of LFP signals is first considered by Biyu Jade He in the entry ► [“Electrocorticogram \(ECoG\)”](#). This entry reviews models of the ECoG and how this surface signal relates to the LFP recorded in depth. The entry also discusses the spectral structure of these signals and their power-law frequency scaling.

The modeling of LFPs is further developed in the entry ► [“Local Field Potentials: Interaction with the Extracellular Medium”](#) by Claude Bedard and Alain Destexhe. This entry reviews models of LFPs by staying as general as possible and includes the electrical nature of an extracellular medium. Both microscopic and macroscopic (mean-field) models of the LFP are considered. It is shown that the frequency-filtering properties of the extracellular medium can fully explain the spectral properties of LFPs (such as power law or $1/f$ scaling).

Methodological Aspects of the LFP

Different methods to record LFPs are described in the entry ► [“Local Field Potential, Methods of Recording”](#) by Andrew Sharott. This entry describes important factors such as the type of electrode, the role of the reference, and the recording conditions. The entry discusses how such factors can be determined to correctly interpret the LFP signal.

In the entry ► [“Resistivity/Conductivity of Extracellular Medium”](#), Scott Lempka and Cameron McIntyre review another set of important biophysical properties that contribute to LFP genesis: the electrical properties of neural tissue, the associated measurements of conductivity, the frequency-filtering properties, as well as the influence of volume conduction.

Finally, in the entry ► [“Current Source Density \(CSD\) Analysis”](#), Daniel Wójcik reviews the physical bases of the CSD analysis, which consists of estimating neuronal current sources from LFP measurements performed by electrodes located at equidistant points in space. Different variants of the CSD analysis are presented and discussed.

Low Frequency Oscillations (Anesthesia and Sleep): Overview

Diego Contreras
Department of Neuroscience, School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

Synonyms

Delta oscillations; Relay mode; Sleep; Sleep oscillations; Sleep spindles; Slow oscillations; Slow rhythms; Thalamic bursting

Definition

The transition from waking to sleep or to anesthesia is characterized by an increase in the amplitude and a decrease in the frequency of the electrical activity recorded in the electroencephalogram (EEG). The spectral composition of the EEG changes from one dominated by low-amplitude fast frequencies in the

beta gamma range to one dominated by the frequency ranges of slow (0.1–1 Hz), delta (1–4 Hz), and sigma (7–15 Hz, which corresponds with sleep spindles) oscillations (da Silva and Schomer 2011). The dramatic changes in the EEG during the transition from waking to sleep correlate with the deafferentation of the forebrain from the external world and the suppression of consciousness. This section describes cellular mechanisms and computer models of these oscillatory processes and their functional consequences. In this overview entry, some critical points are discussed about the organizations of these rhythms in slow wave sleep and anesthesia.

Detailed Description

Background

Slow sleep rhythms are generated within the vast networks connecting thalamus and cortex (Steriade et al. 1994; McCormick and Bal 1997). The main building blocks of thalamocortical circuits (Steriade 2003; Jones 2007), which are essential to understanding the basic principles of rhythm generation (Fig. 1), are (i) reciprocal excitatory glutamatergic connections between cortical pyramidal cells and thalamocortical neurons; (ii) collaterals of excitatory thalamocortical and corticothalamic axons onto reticular thalamic cells, which are established as these axons cross the reticular nucleus on their way in and out of the thalamus; and (iii) inhibitory connections from reticular thalamic cells onto thalamocortical neurons. Reticular thalamic neurons surround the thalamus in its dorsal and lateral surfaces and do not project to the cerebral cortex but project only back into all other thalamic nuclei (Ramon y Cajal 1911). The reciprocal excitation and feedback inhibition combined with various degrees of convergence and divergence are essential to the generation, distribution, and synchronization of the rhythms that characterize sleep and anesthesia (Jones 2001).

Cellular Mechanisms

The single most important cellular mechanism underlying the dramatic transformation in brain

Low Frequency Oscillations (Anesthesia and Sleep): Overview, Fig. 1 A summary of the basic thalamocortico-thalamic circuit: 1. Reciprocal excitatory (glutamatergic) connections between thalamocortical (TC) and cortical (Cx) neurons. 2. Both ascending and descending axons leave collaterals in the reticular nucleus (RE). 3. RE neurons are exclusively GABAergic and project topographically only back into the dorsal thalamus (not to cortex). The three cells used for the schematic were recorded intracellularly in vivo and filled with biocytin

state during the transition from waking to sleep, or to anesthesia, is the change in firing mode of thalamocortical cells (Fig. 2) from tonic to bursting (Llinas and Jahnsen 1982; Jahnsen and Llinas 1984c; Steriade and Llinas 1988; Steriade et al. 1994; McCormick and Bal 1997). At depolarized membrane potentials (V_m) during activated brain states, such as waking, thalamocortical neurons respond to inputs with spike trains that reflect the amplitude and time of the inputs (Deschenes et al. 1984; McCormick and Feese 1990; McCormick and Huguenard 1992). The membrane hyperpolarization that results from the reduction in cholinergic and adrenergic input during the transition from waking to sleep (Oakson and Steriade 1982; Steriade et al. 1982, 1990; Lu et al. 1993; Steriade 1993) removes inactivation of T-type calcium channels (Jahnsen and Llinas

1984a; Nowycky et al. 1985; Coulter et al. 1989; McCormick and Huguenard 1992; Gutierrez et al. 2001). When fully de-inactivated, T-channels are capable of generating an all-or-none calcium spike, known as a low-threshold spike (LTS) because it is triggered at thresholds 10 mV lower than the sodium action potential (Deschenes et al. 1982; Llinas and Jahnsen 1982). The LTS in turn generates sufficient depolarization to trigger a high-frequency (100–300 Hz) burst of sodium action potentials (Llinas and Jahnsen 1982; Deschenes et al. 1984; Jahnsen and Llinas 1984b).

The amplitude of the LTS and, therefore, of the resulting burst of sodium action potentials depend on the proportion of T-channels that are de-inactivated (Deschenes et al. 1982, 1984; Coulter et al. 1989; McCormick and Huguenard 1992), which reaches 100% at the hyperpolarized V_m of late stages of sleep and deep anesthesia.

The mechanism by which LTS bursts are triggered changes throughout the progressive stages of sleep. This is due to the progressive hyperpolarization of thalamocortical cells as sleep (Hirsch et al. 1983) or anesthesia (Contreras and Steriade 1997a) deepens and EEG activity becomes larger and slower (Fig. 3). At early sleep stages, when sleep spindles are the most conspicuous feature of the EEG, thalamocortical cells are still relatively depolarized and T-channels are not fully de-inactivated. De-inactivation depends on the phasic strong chloride-dependent GABAA IPSPs generated by the inhibitory input from reticular thalamic cells during sleep spindles (von Krosigk et al. 1993; Bal et al. 1995; McCormick and Bal 1997). During spindles, LTS bursts are generated as rebound bursts at the offset of these large GABAA IPSPs. At later, deeper (defined by the higher threshold to wake up) stages of sleep, thalamocortical cells are further hyperpolarized and T-channels are fully de-inactivated. At this stage, T-channels are activated by the depolarization caused by the cationic inward rectifier current IH (McCormick and Pape 1990). IH is voltage dependent and activated at the hyperpolarized levels of deep sleep and deep anesthesia. This IH-dependent depolarization, which is a ubiquitous property of thalamocortical cells (Dossi et al. 1992), triggers an LTS and a spike burst, at the

Low Frequency Oscillations (Anesthesia and Sleep): Overview, Fig. 2 This figure shows a thalamocortical neuron, filled with biocytin (*right*) in vivo, responding to synaptic activation (*top three traces*) and direct current injection (*bottom four traces*) through the microelectrode.

Hyperpolarization switches firing mode from tonic to bursting in both cases. *Bottom trace* shows a rebound burst, a burst generated at the termination of a hyperpolarizing pulse (From Contreras and Steriade 1995)

Low Frequency Oscillations (Anesthesia and Sleep): Overview, Fig. 3 The transition from waking to sleep is characterized in the EEG by a transition from high-frequency (~40 Hz) low-amplitude activity to low-frequency (<15 Hz) high-amplitude oscillations. TC cells recorded simultaneously with the EEG show the transition from tonic, relay mode of firing during the waking state to the bursting, all-or-none mode of firing, incompatible with information transfer to the cerebral cortex. In addition, as

shown in the figure, the bursting mode of firing is associated with the presence of global slow oscillations that are synchronized and widespread over large cortical and thalamic territories (the figure shows how activity is synchronized only during sleep between areas 4 and 5, for example). The high-amplitude, synchronized oscillatory activity together with the thalamic bursting mode of firing disconnect the cortex from the outside world during sleep (From Contreras and Steriade 1997a)

end of which, the membrane returns to its hyperpolarized level and reactivates IH, thus restarting a rhythmic cycle at the delta frequency range (McCormick and Pape 1990; Dossi et al. 1992; Nunez et al. 1992a). At the deep stage of sleep where thalamocortical cells generate delta oscillations, the EEG is also dominated by large amplitude rhythmic waves at the delta frequency. However, it is not clear what the relationship is, if any, between the intrinsically generated delta oscillations of thalamocortical cells and the cortical generators of delta oscillations when this rhythm is the predominant feature of the EEG (Amzica and Steriade 1998; da Silva and Schomer 2011; Carracedo et al. 2013).

A fundamental consequence of the progressive hyperpolarization of the Vm of thalamocortical cells throughout sleep (Fig. 3) is that, at the deep sleep stages when delta oscillations dominate the EEG (Fig. 3), the Vm is at or below the reversal potential for chloride, and therefore sleep spindles cannot occur. This leads to an incompatibility of sleep and delta rhythms in thalamocortical cells, with sleep spindles characterizing early stages when the Vm is still relatively depolarized and delta oscillations characterizing late stages when the Vm is very hyperpolarized (Nunez et al. 1992b).

Functional Consequences of Slow Rhythms

Three main consequences result from the transition in firing mode from tonic to bursting during the transition from waking to sleep or anesthesia:

1. *Unreliability of Responses.* Rather than reliable and predictable responses to sensory, motor, or cortical input, thalamic cells respond to inputs with all-or-none bursts of spikes which bear little information about the incoming input. Furthermore, because voltage-dependent inactivation of T-channels lasts tens of milliseconds, bursting responses to depolarizing inputs can only occur at low frequencies and therefore represent a strong frequency filter to incoming inputs (McCormick and Feese 1990).
2. *Rhythmicity.* The transition to burst firing brings about slow rhythmic activity in thalamocortical networks. Three main slow rhythms characterize sleep and anesthesia: sleep spindles (7–15 Hz), delta oscillations (1–4 Hz), and slow oscillations (0.1–1 Hz). Such oscillatory activity requires participation of burst firing by thalamocortical cells and therefore extends the role of thalamic burst firing to the deafferentation of the forebrain. Indeed, in addition to the bursting properties described above, most thalamic spike bursts occur NOT in response to stimuli but, instead, as part of large oscillatory networks, further hindering thalamocortical relay of inputs (Steriade et al. 1994; Steriade 2000).
3. *Synchronization.* An inevitable consequence of thalamic burst firing and slow rhythm generation is the broad synchronization of thalamocortical networks (Contreras and Steriade 1997a, b). By virtue of the divergence and convergence of connections between reticular thalamic and thalamocortical cells, between thalamocortical and cortical neurons and within cortical networks, the strong bursting activity entrains large networks into the slow oscillations of sleep and anesthesia (Amzica and Steriade 1995).

As a result of the above three factors, the reliably responding, rapidly engaged thalamocortical networks that sustain information processing and consciousness in the awake state are transformed into networks that are slow and unreliable in responding and are engaged mostly in slow and synchronized oscillations. These oscillations are incompatible with information processing and ultimately determine the deafferentation of the forebrain during slow wave sleep and anesthesia (Steriade 2000).

Anesthesia and Slow Waves

In contrast with the organized and sequential arrangement of oscillations during sleep, anesthetics mimic and exaggerate one or more rhythmic patterns of sleep in different proportions. For example, during barbiturate anesthesia, the EEG shows spindles most prominently and virtually no delta or slow oscillations. Furthermore, under barbiturate anesthesia, spindle frequency is reduced and

duration increased with respect to naturally occurring sleep spindles. In contrast, ketamine-xylazine generates a strong and exaggerated slow oscillatory pattern on top of which rapid spindles may be triggered. In addition, the slow rhythm during ketamine-xylazine may reach frequencies above 1 Hz and may be confused with EEG delta waves. Urethane anesthesia generates a very stable pattern of slow oscillations with prolonged depolarizing and hyperpolarizing phases but very little spindle or delta oscillations. The combination of propofol and fentanyl produces a rich combination of rhythms including slow oscillations, occasional spindles, and delta waves. Detailed descriptions of oscillatory patterns under different anesthetics are far beyond this section.

Model Reproducibility: Overview

Sharon M. Crook
School of Mathematical and Statistical Sciences
and School of Life Sciences, Arizona State
University, Tempe, AZ, USA

Definition

The ability to reproduce an experimental result is the foundation of scientific inquiry. Similarly,

computational studies need to be reproducible to serve the advance of science. However, computational scientists often find it difficult to reproduce published computational results. Here we provide an overview of efforts to support model reproducibility in computational neuroscience.

Detailed Description

Reproducing the simulation results of computational models and establishing the provenance of results should be straightforward given that computational studies do not suffer from the measurement errors seen in the experimental sciences. However, computational science has its own challenges for reproducibility, which are described well by Crook et al. (2013). In particular, issues such as the sensitivity of a model to numerics or the publication of models that are computationally under-specified lead to the need for criteria for successful model reproduction in many cases. These authors also make distinctions among:

- *Replicability*, where the same code and tools are used to reproduce results
- *Cross-replicability*, where the same model is used but implemented using different software
- *Reproducibility*, where a new model is implemented and produces the same scientific result

As noted in Crook et al. (2013), the boundary between cross-replicability and reproducibility is not always clear, but all efforts along this continuum of reproducible research contribute to advances in the computational sciences.

Model Sharing

Model sharing provides a means for promoting replicability and transparency in the computational sciences. For many reasons, the best infrastructure for sharing models involves curated model repositories such as ModelDB (Migliore et al. 2003), the BioModels Database: a Public Repository for Sharing Models of Biological Processes (Li et al. 2010; Vijayalakshmi et al. 2013), the Physiome Repository (Yu et al. 2011), and Open Source Brain (Gleeson et al. 2019).

Simulator Independent Specification of Models and Simulations

There are a number of ongoing efforts in support of cross-replicability with the aim of providing declarative descriptions of models that are simulator independent. Many of these efforts focus on the use of Extensible Markup Language (XML) technology (Bray et al. 1998) as an ideal representation for complex models.

The Systems Biology Markup Language (SBML) (Hucka et al. 2003) and CellML (Lloyd et al. 2004) are two popular languages for describing systems of interacting biomolecules that comprise models that are often used in systems biology. Both languages also can be used for describing more generic dynamical models, including those in neuroscience. FieldML follows a similar approach but focuses on multivariate spatiotemporal models and models based on the finite element method. NeuroML (Goddard et al. 2001; Crook et al. 2007; Gleeson et al. 2010) differs from these languages in that it is domain specific, where neuroscience concepts like cells, ion channels, and synapses form the basis for objects described in the language. NineML is another domain-specific language that focuses on descriptions of spiking neural networks. Additionally, the Simulation Experiment Description Markup Language (SED-ML) (Köhn and Le Novère 2008) provides a language for describing the details of simulation experiments. These different markup languages are complementary, and together they cover the different spatial scales for the majority of models in neuroscience.

Other efforts focus on code-based approaches for simulator independent model descriptions. PyNN is a Python-based, simulator independent language for building neuronal network models then simulating the model on any simulation platform that PyNN supports such as NEURON, NEST, and Brian (Davison et al. 2009).

The International Neuroinformatics Coordinating Facility, or INCF, advocates for FAIR (Findable Accessible Interoperable Reproducible) principles across all of their projects and activities including neuroscience data and models. In support of this effort, the organization provides a process for the formal endorsement of community standards, including two for describing models, NeuroML and PyNN.

Improved Research Reporting

In the systems biology community, MIRIAM (Minimum Information Required in the Annotation of Models, <http://co.mbine.org/standards/miriam>) is a community-level effort to provide a set of guidelines for use with any structured format for sharing models. The idea of using best practices and some required metadata for sharing and publishing models is outlined by Novère et al. (2005). All of these requirements can be adapted readily to models in neuroscience. Nordlie et al. (2009) conducted a survey of neuronal network models in the literature and found that current approaches are diverse and inadequate. These authors propose the adoption of best practices for model descriptions in publications, recommending the inclusion of the hypothesis, model derivation, model description, implementation details, model analysis, and model justification. They also provide a concise tabular format for summarizing network models in publications. Publication standards such as those discussed by Le Novère et al. and Nordlie et al. ensure that all possible model details are provided; however, it is important to be aware of the limits of replicability and the impact on reproducibility.

Definition

Physical-, molecular-, and cellular-scale understanding is not only the first step in the long ladder of multiscale modeling for clinical translational application, it is also the critical scale: “Where the rubber meets the road.” The idiom from automotive engineering refers to the critical endpoint where all the ancillary engineering – fuel system, chassis, pistons, etc. – is finally tested. In the realm of translation, this point comes when we translate basic research results to the clinical setting. The physician intervenes at the molecular scale, using pharmacological agents to alter physiological activity only observed at far higher scales: the macroscopic realms of clinical tests and of signs and symptoms. The surgeon intervenes at a physical scale, for example, tying off or filling up a vascular aneurysm to prevent its bursting in the brain.

Given the vast scale gap between molecular or physical treatments and macroscopic outcome, there is enormous difficulty in understanding causal relations, so as to design better drugs and better drug combinations. Multiscale modeling can help make these connections in order to provide a basis for rational pharmacological or surgical treatment.

Detailed Description

This section includes entries of three types:

Techniques: These simulations are performed largely using techniques used elsewhere in computational neuroscience. However, some techniques have been introduced or expanded in the context of their use in translational studies.

Locations: Partitioning of the nervous system can be done at many scales, from organelle to major brain area.

Diseases: We make note of a few neurological and psychiatric illnesses that have been examined at this scale.

Techniques

The standard techniques of molecular and cellular computational neuroscience are utilized for clinical and translational modeling. The techniques that are applicable to simulation at the molecular and cellular level are listed here by their coverage in the entries of this encyclopedia (loosely grouped from micro to macro):

Stochastic Simulators

- [Gillespie Algorithm for Biochemical Reaction Simulation](#)
- [Deterministic Reaction-Diffusion Simulators](#)
- [Bimolecular Reactions, Modeling of](#)
- [Equivalent Cylinder Model \(Rall\)](#)

In this section, we add three additional methods that have been applied to clinical translational problems.

► [“Polypeptide and Protein Modeling for Drug Design”](#) takes us down to the lowest of the

multiple scales used in computational neuroscience. Polypeptide modeling largely utilizes ball-and-spring modeling, staying above the level of quantum mechanical representations. Individual atoms or atomic groups (e.g., amino acids) are represented as moving in a force field largely determined by the chemical bonds connecting them. This research has direct importance for clinical translation because the lock-and-key fit of a ligand (a drug) to a target is dependent on the physical relations of the interacting species.

“Application of Declarative Programming in Neurobiology to Decipher Normal and Pathological Processes” demonstrates the novel use of a declarative programming language to address problems in Alzheimer’s disease and in fear conditioning. Declarative programming is distinguished from the familiar imperative programming languages which we commonly utilize. Imperative programs implement an algorithm. Declarative programs describes relationships between elements, defining what computations are possible among these elements.

► [“Biomechanical Modeling of Traumatic Brain Injury”](#) provides physical-level models that consider the material properties of tissue, its geometry, and boundary conditions for stresses applied to the head, using finite element methods to predict injury from impact.

Locations

Disease strikes at many locations and at many scales. Parsimony and clinical efficacy depend on finding the proper scale and proper locus for clinical investigation and for clinical intervention – in some cases these are not the same location. A recent example from oncology is illustrative: a renal cancer and a leukemia were previously classified according to organ system and therefore treated by different subspecialists with different therapeutic approaches. These cancers have now been found to share the same tumor mutation and to benefit from similar treatments. As in this oncology example, protean neurological diseases will also express widely. For example, diseases of mitochondria such as MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes) and MERRF (myoclonic epilepsy with ragged red fibers; the ragged fibers

being broken mitochondria) produce neurological disorders across many neural systems, beyond the already broad scope of their acronyms (DiMauro et al. 2013).

In addition to connoting locations in the brain and body (macroscale), disease localization also needs to consider the locus in the cell: particular organelles such as mitochondria, particular classes of molecules such as ion channels, and particular specialized subcellular spaces such as synapses and spines. Some of these locations are covered elsewhere in these volumes: see ► [“Synaptic Dynamics: Overview”](#) and ► [“Dendritic Spines”](#). It is to be expected that disorders of spine shape, and of proteins involved in synaptic plasticity, will produce neurological or psychiatric disorders. In this section, we consider the modeling of pharmacotherapeutic manipulation of ion channels in ► [“Neuropharmacological Modeling Alterations in Ionic Homeostasis”](#) and ► [“Neuropharmacological Modeling, Pharmacogenomics and Ion Channel Modulation”](#).

A literal route to clinical application is described here in ► [“Brain Extracellular Space: A Compartment for Intercellular Communication and Drug Delivery”](#). The blood-brain barrier and the extracellular space represent the major pathways for delivery of pharmacological agents. Due to therapeutic index (therapeutic concentration/toxic concentration ratio), it is important to consider how a particular drug can be delivered so as to arrive at adequate concentrations at the site of disease, without being present at excessive concentration at other locations (Brick and Erickson 2013).

At the cellular level, neurological disease has substantial overlap with disease in other excitable tissues. It is particularly valuable to consider the extensive work that has been done in cardiology, here represented by ► [“Cardiac Excitable Tissue Pathology \(Ion Channels\)”](#) and ► [“Cardiac Excitable Tissue Pathology \(Ischemia\)”](#). Cardiology models are generally more mature than those in neurology. They also have direct analogies to diseases of the brain, e.g., myocardial infarction and stroke, arrhythmias, and epilepsies. Similarly, excitable tissue is important in the islets of the pancreas and in other endocrine systems, where production and release of hormone are directly

analogous to production and release of neurotransmitters: see entry on ► [“Endocrine Cell Function and Dysfunction”](#). A broader physiological perspective, relevant to many of these cell types, is presented here in ► [“Neuropharmacological Modeling Alterations in Ionic Homeostasis”](#).

Many neurological diseases present outside of the brain or involve the brain in its association with the body. In particular, the enteric nervous system (ENS) and autonomic nervous system (ANS) are prone to disorders (Rao and Gershon 2016) and will be important areas for modeling in the future. In the present section, we feature an entry on ► [“Pathological Changes in Peripheral Nerve Excitability”](#), to consider disorders in the peripheral nervous system (PNS). It is important to note that myopathies (muscle diseases) also fall within the bailiwick of neurology and will benefit from modeling, some of which can be borrowed from the cardiology literature.

At the subcellular level, signaling occurs through second and third through nth messengers. There has been considerable modeling at this scale (Blackwell 2013), but not as much looking at dysfunction. These topics are covered in detail in the entry on ► [“Biochemical Signaling Pathways and Diffusion: Overview”](#). Particular note should be made of the major role of calcium as a second messenger, covered in eight entries in that section. Certainly, dysregulation of calcium control will play a major role in the production and expression of disease that has yet to be elucidated by modeling. A review of the key role of calcium in Alzheimer’s disease, Parkinson’s disease, and Huntington’s disease and the current modeling efforts are presented in the entry on ► [“Calcium Dysregulation in Neurodegenerative Diseases”](#).

At the subcellular and intracellular level, neurons metabolic dependence on astrocytes is modeled in ► [“Brain Energy Metabolism”](#). The entry details how dysfunction, particularly glucose hypometabolism in neurodegenerative diseases, could lead to cognitive impairments. It includes a detailed example of a three-compartment metabolic network model of energy metabolism and the challenges of developing a spatial model.

A multiscale model of neuroinflammation is described in the entry ► [“Neuroinflammation,](#)

[Glia, and Cytokines: Networks of Networks](#)". It involves modeling networks of molecular interactions at the subcellular level, which influence a network of cell states that then feed into a network of inflammation states at the tissue level. Complex network interactions can lead to unexpected results. The entry describes several modeling approaches including machine learning, dynamic systems, and control theory that reveal underlying properties of the system.

All disease is to a greater or lesser extent multifactorial. Patient susceptibility is determined in substantial part by the genome and its control, as well as by the epigenome (and metagenome, representing additional genomes that are involved (mitochondrial, bacterial – commensal or pathological, viral). In a neuron, communication between genome and synapse is particularly complex, insofar as this is information flow between the organism's two primary loci of information storage. Synaptic changes depend on elaboration, transport, and insertion of membrane proteins, which start with signals at the synapse that trigger changes in transcription. In the present section, we cover the role of second messengers in providing communication with the cell nucleus: ► ["Transcriptional Control Dysfunction, Modeling"](#), evaluating potential pathology in the linkage between the cell and its nucleus at the molecular and organelle scales.

Diseases

Evaluation of individual diseases is the natural approach for clinical translation – as an end goal we want to know how to treat a particular disease or even a particular patient (personalized medicine) or subgroup of patients (precision medicine). We highlight here four diseases, although there are several others where some cellular/molecular modeling progress has been made and many more where such progress is greatly needed.

A model of molecular dependencies in Alzheimer's is presented in "Application of Declarative Programming in Neurobiology to Decipher Normal and Pathological Processes". Examples of modeling the role of calcium in this disease are given in ► ["Calcium Dysregulation in Neurodegenerative Diseases"](#).

As a lens through which to view computational neuroscience, disease modeling presents a number of difficulties. First, diseases are generally multi-organ, both in production and in expression. For example, we present here an entry on ► ["Brain Ischemia and Stroke"](#). Stroke is most often caused by atherosclerosis, a disease of blood vessels. A translational model would ideally include the cellular changes of the arterial wall and the changes in hemodynamics, along with factors that include the blood-brain barrier (which breaks) and the role of a broad dispersion of harmful neurohumoral agents. Stroke frequently co-occurs with myocardial infarction (MI). These coincident disorders, in the brain, heart, and local microvasculature, affect one another, e.g., MI reduces cardiac output and therefore increasing the extent of an incipient stroke (Gan and Ramani 2008). Another difficulty in providing a unified model of a disease is that the disease may involve many disparate variants: hemorrhagic vs. bland stroke, thrombotic vs. embolic stroke, and cortical stroke (gray matter) vs. internal capsule (white matter) stroke.

As mentioned in the ["Definition"](#) section above, modeling at physical, molecular, and cellular levels is only the lowest rung in the multi-scale ladder of both downward and upward causality. Disparate viewpoints at different scales represent a challenge but are a necessary stage in the development of future unified multiscale views, as can be illustrated by the case of epilepsy – contrast the entry in the section: ► ["Epilepsy: Abnormal Ion Channels"](#) with the perspective presented in entries on ► ["Epilepsy: Computational Models"](#), ► ["Slow Oscillations and Epilepsy: Network Models"](#), and ► ["Epilepsy, Neural Population Models of"](#).

How are we to build multiscale models out of these disparate pieces? Ideally it would be possible to embed one scale within the model for the higher scale, thereby creating a single unified multiscale model. In many cases this is not possible, so that the models remain separate, with each level informing the other via emergent properties discovered at the lower level. In the case of epilepsy research, emergences from the effect of a drug on a detailed model of an ion channel can be used to change the parameterizations of an ion

channel, which could then be directly embedded in a compartmental model. Emergences from the compartment model can then be used in a reduced model or to modify an integrate-and-fire model. Either of these models (or both as in a hybrid network) can be directly embedded to produce large network models. Emergences from the network can then be used to modify a mean-field model. While this upward sequence is difficult, the downward sequence is even more difficult: we want to follow the scales back down in order to apply lessons learned from the population model in order to eventually suggest changes to drug effect at the polypeptide level.

Conclusions

These initial efforts aimed at understanding the base scale of physical, molecular, and cellular interactions for understanding brain disease should be considered in the context of the wider field of computational systems biology, a field concerned with multiscale modeling across organ systems and medical specialties. Systems biology has been catapulted forward with the realization that the massive amounts of data being collected as genomes, proteomes, and other omes will not be interpretable without contexts, contexts that can only be provided by sophisticated computational models. Further future hope springs from the potential of computer simulation to provide personalized or precision medicine; physiological data from a particular patient would be used to adapt simulation parameters for simulation, just as anatomical data for a particular patient is currently used to provide specifics of beam targeting in radiation therapy.

Motoneurons and Neuromuscular Systems: Overview

Sharmila Venugopal

Department of Physiology, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA, USA

Department of Integrative Biology and Physiology, University of California, Los Angeles, Los Angeles, CA, USA

Definition

Motoneuron models are mathematical representations of motoneuron structure and function. Neuromuscular models represent computational models of neural components integrated with muscle models at various levels of detail and complexities. These models provide a computational framework for investigating neural control of movement. Together, motoneuron and neuromuscular models can guide the development of biomimetic neuromuscular control systems and neural prostheses.

Detailed Description

Motor neurons (or motoneurons) are the final common pathway for all neural drive to the skeletal musculature. Each motoneuron innervates one or more muscle fibers and the cell bodies of motoneurons are somatotopically organized in both vertebrates and invertebrates. Motoneurons were among the first neurons to be studied in great detail by experimentalists largely due to their unique position as output neurons of the nervous system. The rich tradition of the experimental work dates back to the early 1900s beginning with the historical work by Sir John Eccles (1903–1997) and Sir Charles Sherrington (1857–1952), followed by a host of physiologists to date whose work has laid the foundations for realistic models of motoneurons.

Like many neurons in the nervous system, motoneurons show repetitive firing behavior in response to excitation. However, like no other neurons in the nervous system, their frequency of spike discharge directly dictates the degree of muscle contraction. In this way, they mediate control of complex behaviors. At the cellular level, they possess complex morphologies that strongly influence their integrative function. They house a rich assortment of intrinsic membrane-bound ion channels that dynamically interact with a wide range of synaptic inputs to produce unique nonlinearities in their membrane properties. The heterogeneity of cellular properties within a motor pool further confers complex population dynamics. Taken together, motoneurons are an important class of neurons in the nervous system that are attractive candidates for modeling in order to gain a deeper understanding of the neural basis of motor control.

In this section, we discuss principles and methodologies used to develop models of motoneurons and motor effectors at various levels of complexities and scales. At the single cell level, articles presented describe two-compartment models ([► Algorithmic Reconstruction of Motoneuron Morphology](#)), more complex multi-compartment models ([► Brainstem Motoneurons, Models of](#)), and morphologically realistic models ([► Compartmental Models of Spinal Motoneurons](#)). Among vertebrate motoneurons, we explicitly address models of spinal ([► Brainstem Motoneurons, Models of](#)) and brainstem motoneurons ([► Computational Models of Motor Pools](#)). We further describe novel algorithms that can generate realistic motoneuron morphologies given a simple set of experimentally derived morphometric parameters ([► Conductance-Based Models of Nonlinear Dynamics in Vertebrate Motoneurons](#)). At the population level, we describe motor pool models ([► Mammalian Motor Nerve Fibers, Models of](#)). We also describe the computational principles underlying models of the muscles ([► Morphologically Detailed Motoneuron Models](#)). Since motor fibers traverse long distances to provide electrochemical signals for these effectors, models of motor nerve fibers and propagation

of electrical signals along them are described (► [Neuromuscular Control Systems, Models of](#)). Lastly, systems-level models of the neural control systems that enable us to perform tasks by providing suitable input to motoneurons are described (► [Physiology and Computational Principles of Muscle Force Generation](#)).

neuronal system. In the absence of noise or perturbation, the neuronal system permanently exhibits one of the regimes. Multistability suggests that by an appropriate choice of perturbation or by resetting the initial state of the system, one could induce a switch from one regime into another.

Detailed Description

Multistable neuronal system can exhibit two or more regimes of activity, depending on its initial state. Both isolated neurons and neuronal networks can exhibit coexistence of several activity regimes. The coexistence of silence, subthreshold oscillations, tonic spiking, and bursting regimes with each other has been observed in a number of theoretical and experimental studies. A multistable neuronal system can show long-lasting responses to short transient signals. Such systems also may respond to perturbations in a state-dependent fashion, demonstrating hysteresis, which is the hallmark of (Nadim et al. 2008). Multistability has clear implications for dynamical memory and information processing in neurons (Marder et al. 1996; Egorov et al. 2002; Durstewitz and Seamans 2006). In the area of motor control, multistability could be a major mechanism of operation of multifunctional central pattern generators (Getting 1989; Venugopal et al. 2007; Briggman and Kristan 2008). On the other hand, multistability can be a pathological feature; for example, seizure regimes can coexist with normal regimes (Ziburkus et al. 2006; Cressman et al. 2009; Frohlich et al. 2010). For the latter, the electrogenic pump has been implicated to play a crucial role (Cressman et al. 2009; Krishnan and Bazhenov 2011).

Multistability can be categorized in terms of the regimes of activity which coexist, e.g., coexistence of tonic spiking and silence (Rinzel 1978; Guttman et al. 1980; Forger and Paydarfar 2004; Hahn and Durand 2001), coexistence of bursting and silence (Malashchenko et al. 2011a, b), coexistence of different bursting regimes (Wang 1994; Butera 1998; Newman and Butera 2010), and

Multistability in Neurodynamics: Overview

Definition

Multistability in neurodynamics is the coexistence of two or more observable regimes of activity, i.e., attractors, in the phase space of a

coexistence of bursting activity and tonic spiking (Canavier et al. 1994; Frohlich et al. 2010; Cymbalyuk et al. 2002; Shilnikov et al. 2005; Malashchenko et al. 2011a). These regimes can coexist in the phase space of a neuronal system if some unstable regime creates a barrier, i.e., a separatrix demarcating a border between the basins of attraction. The mechanism underlying multistability can also be described and classified in terms of the unstable regime that forms the barrier (Rinzel 1978; Guttman et al. 1980). One of the key ingredients of such descriptions is the identification of the transitions, i.e., bifurcations, at which the unstable regimes appear and disappear. Ubiquitously, a separating regime is either a saddle equilibrium or a saddle orbit (Rinzel 1978; Malashchenko et al. 2011a; Barnett et al. 2013; Marin et al. 2013). For example, the stable manifold of the saddle equilibrium separates tonic spiking and silence observed in the simplified model of the cerebellar Purkinje neurons (Loewenstein et al. 2005; Fernandez et al. 2007), and the stable manifold of the saddle periodic orbit is a cause of bistability of spiking and silence in the giant squid axon (Rinzel 1978; Hahn and Durand 2001).

The methods developed in the bifurcation theory allow one to investigate stability of, evolution of, and transitions between the silent and oscillatory regimes of neuronal models in response to variation of the system's parameters (Kuznetsov 2004; Terman and Ermentrout 2010; Izhikevich 2010). Application of these methods identifies and explains the mechanisms supporting multistability under normal and pathological conditions (Rinzel 1978; Guttman et al. 1980; Forger and Paydarfar 2004; Gutkin et al. 2009; Hahn and Durand 2001; Krishnan and Bazhenov 2011; Shilnikov et al. 2005; Fröhlich and Bazhenov 2006; Cressman et al. 2009; Cymbalyuk and Shilnikov 2005; Malashchenko et al. 2011a, b).

Neural Population Models and Cortical Field Theory: Overview

Ingo Bojak

School of Systems Engineering, University of Reading, Reading, UK

The term neural population models (NPMs) is used here as catchall for a wide range of approaches that have been variously called neural mass models, mean field models, neural field models, bulk models, and so forth. All NPMs attempt to describe the collective action of neural assemblies directly. Some NPMs treat the densely populated tissue of cortex as an excitable medium, leading to spatially continuous cortical field theories (CFTs). An indirect approach would start by modelling individual cells and then would explain the collective action of a group of cells by coupling *many* individual models together. In contrast, NPMs employ collective state variables, typically defined as averages over the group of cells, in order to describe the population activity directly in a *single* model. The strength and the weakness of his approach are hence one and the same: simplification by bulk. Is this justified and indeed useful, or does it lead to oversimplification which fails to capture the phenomena of interest?

In ► [“Mesoscopic Anatomy and Neural Population Models,”](#) Liley explains that the anatomy of the brain is organized into connected modules at the mesoscopic level, which can serve as a biological substrate for NPMs. In ► [“Neuropercolation and Neural Population Models”](#) and ► [“Neural Mass Action,”](#) Kozma describes how this undergirds coherent neural activity. Brunel and Hakim demonstrate in ► [“Population Density Model”](#) and ► [“Fokker-Planck Equation”](#) how NPMs can be derived mathematically from existing descriptions of individual cells, and in ► [“Stochastic Neural Field Theory,”](#) Bressloff shows this for the CFT variant as well. Liley then introduces the general NPM approach in ► [“Neural Population Model,”](#) and Hutt the CFT variant in ► [“Neural Field Model, Continuum.”](#)

Some historically important and/or particularly popular NPMs are showcased in ► [“Amari Model”](#) by Potthast, ► [“Down Under Neural Population Models”](#) by Liley, ► [“Jansen-Rit Model”](#) by Knösche, and ► [“Wilson-Cowan Model”](#) by Kilpatrick.

The modelling of connectivity in NPMs has been a topic of considerable development over the years and is covered in ► [“Propagator, Axonal”](#) and ► [“Synaptic Connectivity in Neural Population Models”](#) by Jirsa, as well as in ► [“Gap Junctions, Neural Population Models and”](#) by Sleight and the Steyn-Rosses. The dynamical properties of NPMs are key for their application to various brain phenomena. The quasi-linear and noise-driven mode is described in ► [“Transfer Function, Electrocortical”](#) by Molaei-Ardekani and Wendling. Transitions in dynamics, for example, to self-sustained oscillations, are discussed in ► [“Bifurcations, Neural Population Models and”](#) by Knösche and ► [“Phase Transitions, Neural Population Models and”](#) by Sleight and the Steyn-Rosses. Whereas the emergence of spatial structure is presented in ► [“Pattern Formation in Neural Population Models”](#) by Hutt and the chaotic regime in ► [“Chaos, Neural Population Models and”](#) by Knösche.

A fundamental strength of NPMs is their ability to predict the data generated by neuroimaging modalities like the electro- and magnetoencephalogram (EEG/MEG) and functional magnetic resonance imaging (fMRI), as described in ► [“Neuroimaging, Neural Population Models for”](#) by Bojak and Breakspear. This allows the comparison of model predictions with experimental data, be it for normal brain function as in ► [“Gamma Rhythm, Neural Population Models of the”](#) by Bojak and ► [“Sleep, Neural Population Models of”](#) by Phillips, under the influence of drugs as in ► [“Anesthesia, Neural Population Models of”](#) by Sleight and the Steyn-Rosses or in disease as in ► [“Epilepsy, Neural Population Models of”](#) by Wendling and Molaei-Ardekani. While many of the methods used to predict the recorded signals are sound and even sophisticated, some of the basics still require substantial improvements, as Einevoll reminds us in ► [“Extracellular Potentials, Forward Modeling of”](#) Much of the work so far has been in forward

prediction with NPMs; however, increasingly it is important to estimate the NPM state and parameters directly from the data. This is elucidated by Moran in ► [“Dynamic Causal Modelling with Neural Population Models”](#) and by Potthast in ► [“Inverse Problems in Neural Population Models.”](#) Finally, it is exciting that NPMs, and CFTs in particular, can be used to model perception and motor control, as Schöner describes in ► [“Embodied Cognition, Dynamic Field Theory of,”](#) with additional remarks by Schöner and Nowak given in ► [“Coordination Dynamics.”](#)

To answer the question that was posed in the beginning, not only is the NPM approach justifiable and has shown itself to be useful; we expect that within a decade or two, NPMs will take their rightful place as the primary means for describing mesoscopic brain activity. The central problem we face at this description level will not be to simulate millions of brain cells in a reasonable amount of time; the central problem is now, and will be then, that we cannot *specify* the properties and interactions of so many brain cells in a biologically meaningful manner and cannot generate actual *human insight* into principles of function from the plethora of individual cell activities. Once the computational power becomes readily available, this realization will be unavoidable. The way forward will be multi-scale descriptions wherein higher levels discard irrelevant detail of lower levels for an effective and efficient description that remains accessible to the human mind. And given their intimate connection to (noninvasive) neuroimaging, we expect that NPMs will play a privileged role in such a future scheme. This section provides a mere snapshot of a field that is currently growing rapidly and will continue to do so in the foreseeable future.

Neuromodulation: Overview

Christiane Linster
 Computational Physiology Lab, Department of
 Neurobiology and Behavior, Cornell University,
 Ithaca, NY, USA

Definition

Neuromodulation refers to the regulation of neural and synaptic function by regulatory extrinsic or intrinsic substances.

Detailed Description

Computational modeling of neural substrates provides an excellent theoretical framework for the understanding of the computational roles of neuromodulation. Neuromodulation can be defined as biophysical processes that serve to modify – or modulate – the computation performed by a neuron or network as a function of task demands and behavioral state of the animal. These modulatory effects often involve substances such as acetylcholine (ACh), norepinephrine (NE), histamine, serotonin (5-HT), dopamine (DA), and a variety of neuropeptides. Modulatory effects are difficult to define, because they often originate from different structures and have different spatial distributions and time courses of action. Because of the wider use of modeling techniques and growing interest in systems neuroscience, the computational role of neuromodulation in information processing has helped elucidate neuromodulatory function, and predictive theories have arisen from computational approaches.

Neuromodulation can be described by its spatial and temporal characteristics, as well as the specific computational function ascribed to it. Spatial characteristics include extrinsic, originating from an area extrinsic to the network under study, or intrinsic, originating from processes within the area under study. The computational functions of extrinsic neuromodulation, such as ACh, NE, 5HT, and DA, are usually considered somewhat global, because they modulate many areas of the brain simultaneously. Classically, ACh has been associated with attentional processes, NE with signal-to-noise modulation, DA with reward learning, and 5HT with sleep-wake transitions. In other cases, modulation is specific to the network under investigation and an integral part of the computations performed within. Second messenger systems, plasticity processes, and gene regulation are examples of such intrinsic modulation. From a functional point of view, neuromodulation is often regulatory, for example, in the cases of second messenger systems or activity-dependent regulation of conductances. In the sensory

systems, neuromodulation is often linked to tuning of receptive fields (ACh) and regulation of signal-to-noise ratio. A third highly important function of most neuromodulators is the regulation of plasticity, via excitability of neurons, synaptic plasticity, and broader modulation of network dynamics.

Exactly how neuromodulation is integrated in computational studies depends widely on the details of implementation of the computational model itself. Effects of neuromodulators can be implemented from the detailed biophysical level, to broader regulation of network parameters in case of more abstract large-scale models. For example, specific effects on voltage-gated channels may be implemented in a biophysical model by changing channel parameters, in a simplified integrate and fire model by changing a related parameter such as firing threshold. Each study chooses the level of detail appropriate to the question asked and data available. For a comprehensive review of levels of implementation of neuromodulation in computational models, we refer the reader to Fellous and Linster (1998). The chapters in this section cover overviews of neuromodulatory computation divided by substance, nature of task, as well as overviews of types of network implementations and specific examples.

Neuromorphic Engineering: Overview

Sylvie Renaud

Institut Polytechnique de Bordeaux, Université de Bordeaux, Talence, France

Definition

Neuromorphic engineering is a recent interdisciplinary field involving biologists, physicists, mathematicians, computer scientists, and engineers to design hardware/physical models of neural systems. It aims at designing silicon-based neural systems for computational or biomedical purposes. The term “neuromorphic” relates to the computational architecture, shaped to model biological neural systems: neuromorphic engineering is by essence strongly linked to computational neuroscience.

Detailed Description

Neuromorphic engineering offers an interesting alternative to computer simulations of neural networks: while main components of computers are high-precision high-speed digital hardware with high-power dissipation, neural components are slow asynchronous computational elements which use a combination of analog and digital signal representations. Neuromorphic systems are hardware implementations that operate in physical time; they are inspired by the structure, function, and plasticity of biological nervous systems. Their design is facilitated by similarities between VLSI (very large-scale integrated circuits) hardware and neural bioware.

Since decades, researchers have been implementing electronic models of neural circuits, following the long history of artificial neural networks that started in the 1950s. Original neuromorphic circuits (Mead 1989) were VLSI systems that used the nonlinear and graded properties of transistors to emulate protein channels in neurons. More recently the term neuromorphic

has been used to describe analog, digital, and mixed analog-digital VLSI as models of neural computation.

Neuron model computation can be either analog, with a continuous-time and continuous-value representation, or digital using numerical algorithms. In both cases, neuromorphic devices classically use spiking (asynchronous binary signal analogs to neural spikes) representation for neuronal communication and learning mechanisms. At the neural network level, synaptic modification mechanisms are usually introduced to model learning and adaptation in neural systems. Furthermore, similar to robustness of neural networks to changes in the environment, dynamic synaptic modification in neuromorphic systems allows gaining a remarkable robustness against transistor-level variations. Whatever the technological support of the neuromorphic electronics, real-time computation is mandatory for systems interacting with a biological environment (sensory or motor).

To date, widely known neuromorphic systems are highly integrated VLSI that emulate sensory transduction (vision, olfaction, audition) or more sophisticated and multimodal neural systems like the head-direction system. Larger neuromorphic systems emerged in the last decade, emulating complex or cognitive biological functions and suggesting new research directions for robotics by the means of biomorphic engineering.

According to the VLSI technology road map, promising low-power and high-density nanoscale technologies, including organic electronics, memristors, or 3D technologies, are expected to fulfill the need for large-scale neuromorphic systems, currently implemented using standard CMOS VLSI technologies. Large neuromorphic systems have performance measures (high density, high speed, low power) that are good enough to enable the study of large-scale and biologically inspired neural networks. Such large networks represent a challenge for computational neuroscience. Researchers have recently started investigating cognitive neuromorphic systems that are able to perform adaptive behaviors and that merge neural fields and single-neuron representations courtesy of the increased computational power of microelectronic devices.

Entries in this section review state-of-the-art neuromorphic engineering computational principles, technologies, and applications. This transdisciplinary research field, at its heart, combines the physics of electronics and biology and algorithms and then engineers it for solving tasks. Despite the many challenges, neuromorphic engineering may hold great promises for a new generation of medicine or industry technologies.

Neuronal Model Optimization: Overview

Astrid A. Prinz
Department of Biology, Emory University,
Atlanta, GA, USA

Synonyms

Neuronal model hand-tuning

Definition

Neuronal Model Parameter Optimization is the process of adjusting the parameters of a computational model of a neuron or neuronal network in order to achieve model activity that mimics that of the living neuron or network being modeled.

Detailed Description

This section contains entries that explain the need for neuron and network model parameter optimization, discuss various optimization methods, describe existing software tools for optimization and visualization of the model databases that result from some of the optimization methods, and discuss related concepts that have emerged from model optimization and exploration efforts over the last few years.

Why Do Neuronal Model Parameters Need to Be Optimized?

Computational models of neurons and neuronal circuits are important investigative tools that allow the study of neuronal signaling and information processing mechanisms that would not be experimentally accessible. However, constructing a model neuron or network requires the specification of numerous parameters, such as maximal conductances, half-activation voltages, and time constants of ionic membrane currents, as well as the strength and dynamical properties of synapses. A complete set of parameters to describe a given neuron or network is virtually never available from experimental data, because some of the parameters cannot be directly measured. Combining parameters measured from different animals is also problematic because almost all parameters vary between animals, and the distributions in the space of parameter sets obtained from different animals are often non-convex, leading to ► [“Failure of Averaging,”](#) i.e., the problem that the set of parameter averages obtained from a distribution of parameter sets can fall outside that distribution in parameter space.

Neuronal models initially constructed from incomplete and averaged parameter sets therefore

usually generate activity that does not match that of the living system to be modeled. Such dysfunctional models then require parameter optimization, either through ► [“Neuronal Model Hand-Tuning”](#) by an expert employing educated guessing and trial-and-error parameter adjustments, or through one of the optimization methods described in this section.

Neuronal Model Optimization Methods

One approach that allows the identification of neuronal model parameter regimes that produce qualitatively different model behaviors (for example, spiking versus bursting versus silence) is ► [“Bifurcation Analysis,”](#) i.e., the use of dynamical systems analysis to determine critical parameters that cause transitions from one behavior to another. Bifurcation analysis is most powerful for models of low dimensionality. For models with many dynamic variables and parameters, the use of bifurcation analysis may therefore require prior model simplification through ► [“Neuronal Model Reduction,”](#) ideally without the loss of essential features of model activity.

A more agnostic approach to studying the dependence of neuronal model activity on the underlying model parameters is ► [“Neuronal Parameter Space Exploration,”](#) i.e., the brute-force computational exploration of many – often tens of millions – of parameter combinations that cover the model’s high-dimensional parameter space. Characteristics of the simulated model activity for each parameter combination are then stored in ► [“Neuronal Model Databases”](#) that can be mined for model versions with the desired activity, and to address general questions about the relationship between model parameters and output.

Less exploratory, more targeted model optimization methods are based on ► [“Evolutionary Algorithms.”](#) They require the definition of a ► [“Neuronal Model Output Fitness Function,”](#) which is a measure for how well a neuron or network model’s activity replicates that of the living system to be modeled. ► [“Multi-objective Evolutionary Algorithms”](#) constitute a class of evolutionary algorithms that simultaneously

optimize models to meet several different objectives, rather than maximizing a single fitness measure. An implementation of evolutionary neuronal model optimization is available in the software tool ► [“Neurofitter.”](#)

Finally, ► [“Hybrid Parameter Optimization Methods”](#) combine several of the above methods of neuronal model optimization to benefit from their respective advantages.

Visualization of Neuronal Model Parameter Spaces

Several of the model optimization methods described in this section produce long lists of parameter sets and their corresponding neuronal model activity that are often collected in ► [“Neuronal Model Databases.”](#) Because the underlying models and their parameter spaces are high-dimensional, it is difficult to analyze how the activity of a model varies across parameter space. This problem is addressed by recently developed methods of ► [“Neuronal Parameter Space Visualization,”](#) including the visualization tool ► [“NDVis-Neuro,”](#) which is designed for the visualization of model databases that cover parameter space with a regular grid of parameter sets.

Beyond Optimization

A number of recent neuronal model optimization efforts, as well as a growing body of experimental data, have revealed concepts that go beyond model optimization in the sense of identifying a single “optimal” model parameter set. Neuronal models and the living systems they mimic display ► [“Neuronal Parameter Non-uniqueness,”](#) meaning that different parameter sets can produce similar and functional neuron or network activity. The subset of parameter space that contains such functional parameter sets is called the “Neuronal Solution Space.” Analysis of the structure of neuronal solution spaces has revealed that parameters do not necessarily vary independently within the solution space, but often show ► [“Neuronal Parameter Co-regulation.”](#)

Apart from asking whether a given parameter set does or does not support functional model

activity, parameter space exploration also allows for the analysis of ► [“Neuronal Parameter Sensitivity,”](#) that is, in which direction and how strongly activity characteristics such as spike frequency depend on model parameters.

Together, the realization of ► [“Neuronal Parameter Non-uniqueness”](#) and the connected concept of “Neuronal Solution Space” have led to the strategy of “Ensemble Modeling,” i.e., the approach of analyzing an entire ensemble of parameter sets and model versions that produce functional activity, rather than focusing on a single “optimal” model version.

Olfaction: Overview

Francesco Cavarretta¹ and Christiane Linster²

¹Department of Biology, Emory University, Atlanta, GA, USA

²Computational Physiology Lab, Department of Neurobiology and Behavior, Cornell University, Ithaca, NY, USA

Definition

Olfaction refers to the sense of smell and the perception of odorants. This process involves

multiple peripheral and central structures of the nervous system, i.e., the olfactory pathway, and ultimately results in the creation of odor images in the brain as well as the generation of motor and behavioral responses. In several decades, olfaction has been investigated experimentally and theoretically, integrating physiological, behavioral, and computational studies. Here we focus on computational models of olfactory processing, showing how they can promote an understanding of olfaction that goes beyond the mere collection of experimental data.

Detailed Description

In natural environments, airborne chemicals stimulate continually the olfactory system,

with unpredictable occurrence in time and space. The olfactory system enables the detection of these odorants out of a chemically noisy environment, extracting relevant odor features, and making a comparison with previously memorized odors.

The multiple circuits forming the olfactory system are thought to contribute distinct computations to odor processing. Figure 1 shows a schematic representation of the most prominent olfactory circuits in mammals. The short-axon (SA), external tufted (ET), and periglomerular (PG) cells form a subnetwork in the juxtaglomerular area, which has been proposed to transform a disorganized odor representation into a concentration invariant and contrast-enhanced one (Cleland and Sethupathy 2006; Cleland 2010). In the next layer, mitral (Mi) and granule (Gr) cells form a reciprocal

Olfaction: Overview,

Fig. 1 Schematic description of olfactory structures. The olfactory sensory neurons (OSN) expressing a common receptor converge onto the common olfactory glomeruli, where they make excitatory synapses with the mitral (Mi), periglomerular (PG), and external tufted (ET) cells. ET, PG, and superficial short-axon (SA) cells are interconnected, forming a subnetwork in the glomerular layer. The high convergence between OSNs and glomerular cells can increase signal-to-noise ratio in the system (Linster and Cleland 2009). PG cells make inhibitory connections with Mi cell primary dendrites, allowing for contrast enhancement of the olfactory signals ahead of the Mi cell response (Cleland and Sethupathy 2006)

excitatory/inhibitory loop, which has been hypothesized to implement the neural substrate for fast oscillations and synchrony (Freeman 1974; Brea et al. 2009). Mi cell axons project to secondary olfactory structures, including the piriform cortex, in a non-topographically organized fashion. In the cortex, Mi axons make distal synapses with pyramidal (Pyr) cells, displaying short-term plasticity (Wilson and Linstner 2008). The extensive excitatory connections between cortical pyramidal (Pyr) cells, known to undergo synaptic plasticity, have long been proposed to implement an associative memory for odor storage (Hasselmo et al. 1990).

Computational models of olfactory processing have provided mechanistic and functional insights into odor perception and learning. Mechanistical models have long focused on generation and maintenance of fast oscillations in the olfactory system, and particularly in the gamma range (e.g., Freeman 1974; Lagier et al. 2004; Li and Cleland 2013). Functional models have focused on computations such as signal-to-noise ratio modulation (e.g., Hasselmo et al. 1997; Linstner et al. 2011), contrast enhancement (e.g., Linstner and Hasselmo 1997; Urban 2002; Cleland and Sethupathy 2006; Cavarretta et al. 2016), and odor learning (e.g., Hasselmo et al. 1990; Wilson and Linstner 2008; Cavarretta et al. 2016, 2018). A prominent subclass of functional models consists of biophysically detailed models, which accounts for diverse neuron types and mechanisms (e.g., Li and Cleland 2013; Gilra and Bhalla 2015; Cavarretta et al. 2018). Many models have focused on linking neural and perceptual processes (e.g., Mandaïron et al. 2006), while others have stayed abstract and predictive (e.g., Brea et al. 2009).

In this section, most entries are about computational modeling of the olfactory bulb. Here, different models address the biophysical mechanisms and network properties of the system (see entries ► [“Biophysical Models of Olfactory Mitral and Granule Cells”](#), ► [“Olfactory Computation in Mitral-Granule Cell Circuits”](#), ► [“Large-Scale Models of the Olfactory Bulb”](#), and ► [“Olfactory Computation in Glomerular](#)

[Microcircuits”](#)), and explain how glomerular and granule cell microcircuits organize odor response in specific patterns of spiking activity (see entries ► [“Olfactory Computation in Mitral-Granule Cell Circuits”](#), ► [“Large-Scale Models of the Olfactory Bulb”](#), and ► [“Olfactory Computation in Glomerular Microcircuits”](#)). Similarly, one entry is dedicated to a model of the insect olfactory system that gives insight into its basic functioning (see ► [“Olfactory Computation in Antennal Lobe and Mushroom Bodies”](#)). The olfactory sensory neurons are treated in one entry, where a mathematical model is proposed to predict the dose-response relationship for generic odor mixtures (see ► [“Olfactory Sensory Neurons to Odor Stimuli: Mathematical Modeling of the Response”](#)). All these entries are then complemented by a short review on information processing in the olfactory bulb (see ► [“Information Processing in the Olfactory Bulb”](#)), and a more speculative entry on the functional implication of neurogenesis in these olfactory areas (see ► [“Olfactory Computation and Adult Neurogenesis”](#)). The olfactory cortex is discussed in the setting of associative networks (see ► [“Olfactory Cortical Associative Memory Models”](#)), providing a review of the existing literature. Furthermore, three examples show of how to cellular and neuromodulatory data can explain behavior (see ► [“Computational Modeling of Olfactory Behavior”](#)), integrating computational modeling of olfactory areas and behavioral data.

Peripheral Nerve Interfaces: Overview

Douglas J. Weber¹, Brian Wodlinger² and Wei Wang²

¹Department of Mechanical Engineering and the Neuroscience Institute, Carnegie Mellon University, Pittsburgh, PA, USA

²Department of Physical Medicine and Rehabilitation, University of Pittsburgh, Pittsburgh, PA, USA

Definition

The peripheral nervous system (PNS) comprises nerve fibers and ganglia located outside of the brain and spinal cord, including 11 pairs of cranial nerves and 31 pairs of spinal nerves. The spinal (or somatic) nerves originate as dorsal and ventral spinal nerve rootlets at their junction with the spinal cord. The dorsal spinal nerve roots contain afferent (sensory) nerve fibers and their cell bodies, which are located in the dorsal root ganglia (DRG). The ventral spinal nerve roots contain efferent (motor) fibers whose cell bodies are located in the ventral horn of the spinal cord. The dorsal and ventral roots merge to form the spinal nerve, which exits the spinal column through the intervertebral foramen. Upon exiting the spine, the nerve divides into dorsal and ventral rami, which may branch further and mix with other nerve fibers to form plexuses (e.g., brachial plexus) and eventually form distinct peripheral nerves and their branches.

Detailed Description

This section begins with background information on the anatomy and physiology of the peripheral nervous system (► [“Peripheral Nerves, Anatomy and Physiology of”](#)) and mathematical models for simulating the biophysical properties of peripheral nerves (► [“Peripheral Nerve Models”](#)). Subsequent entries describe devices and signal processing methods for acquiring and analyzing electrical signals from peripheral nerves.

Techniques for stimulating activity in peripheral nerve fibers are also described. This section also describes several research and clinical applications based on peripheral nerve recording and stimulation techniques.

Peripheral Nerve Interface Methods and Applications

Interfaces to the peripheral nervous system have long been considered of medical value, beginning in ancient Egypt where the pain-relieving properties of the electric catfish were discussed and continuing with the Mediterranean electric ray and torpedo fish. The nineteenth century saw renewed interest in electrical stimulation of the PNS due to dramatic advances in the understanding of electricity. Only relatively recently, however, through the pioneering modeling work of researchers like Hodgkin and Huxley, and those that have expanded and continued their work, have we begun to understand the PNS well enough to design safe and effective interfaces to it.

A wide variety of interface technologies has been developed to record or stimulate activity in peripheral nerves. Most interfaces rely on electrodes placed on the nerve surface (epineural) or penetrate the interior of the epineurium (intraneural) of the nerve (► [“Peripheral Nerve Interface, Intraneural Electrode”](#); ► [“Peripheral Nerve Interface, Epineural Electrode”](#); ► [“Peripheral Nerve Signal Processing, Multipole Cuff Methods”](#); ► [“Peripheral Nerve Interface, Regenerative”](#)).

Peripheral nerve interface technologies have been applied to the diagnosis or treatment of a wide range of medical conditions. Examples of diagnostic applications include electromyography and nerve conduction tests used to identify and localize nerve damage caused by carpal tunnel syndromes, diabetic neuropathies, and other injuries or diseases (► [“Peripheral Nerve Interface Applications, EMG/ENG”](#)).

Electrical stimulation of peripheral nerve fibers is used to evoke activity in sensory, motor, and autonomic fibers. The cochlear implant is a highly successful example of a sensory prosthesis that restores hearing to people with profound hearing

loss due to damage to the hair cells in the cochlea (► [“Peripheral Nerve Interface Applications, Cochlear Implants”](#)). Electrical stimulation of cutaneous nerve fibers with TENS/PENS devices is used to treat a variety of pain syndromes (► [“Peripheral Nerve Interface Applications, Neuropathic Pain”](#)). Other types of sensory prostheses are being developed (► [“Peripheral Nerve Interface Applications, Sensory Restoration”](#)), for example, to provide tactile and proprioceptive sensations to users of prosthetic limbs.

Summary

The highly structured nature of the peripheral nervous system makes it amenable to computational modeling. Advances in these interfaces have already made a profound impact on modern medical technology including cochlear implants (► [“Peripheral Nerve Interface Applications, Cochlear Implants”](#)); techniques to support bladder, bowel, and sexual function; and vagal nerve stimulation (► [“Peripheral Nerve Interface Applications, Vagal Nerve Stimulation”](#)). New techniques currently being investigated will address a variety of disorders throughout the body including obesity (► [“Peripheral Nerve Interface Applications, Obesity”](#)), neuropathic pain (► [“Peripheral Nerve Interface Applications, Neuropathic Pain”](#)), sleep apnea (► [“Peripheral Nerve Interface Applications, Sleep Apnea”](#)), and sensory restoration in amputees (► [“Peripheral Nerve Interface Applications, Sensory Restoration”](#)). The interfaces themselves come in a diverse array of forms from simple cuff electrodes (► [“Peripheral Nerve Interface, Epineural Electrode”](#)) which wrap around the nerve to more complex regenerative electrode arrays (► [“Peripheral Nerve Interface, Regenerative”](#)), and utilize many advanced stimulation and signal processing techniques (► [“Peripheral Nerve Signal Processing, Denoising”](#)).

Peripheral nerve interface technologies hold great promise in the diagnosis and treatment of a wide range of neurological disorders. Research in this area requires significant collaboration between researchers in computational modeling, neuroscience, biomedical engineering medicine, and physiology.

Phase Response Curves: Overview

Carmen C. Canavier

Department of Cell Biology and Anatomy, LSU Health Sciences Center, New Orleans, LA, USA

Detailed Description

Phase response curves (PRCs, alternatively phase-resetting curves) are a powerful way of characterizing and explaining the behavior of

nonlinear oscillators without knowing anything about their specific internal dynamics. The phase response curve represents the shortening or lengthening of the cycle period caused by an input depending upon at what point (phase) within the cycle an input is received. In contrast, for a linear time invariant system, the effect of an input is independent of when it is applied. No matter whether the oscillations represent the flashing of fireflies, a pendulum-based clock, a cardiac cell, or a neural oscillator, the phase response curve predicts the phasic relationship of the oscillator to periodic forcing or to coupling within a network of other oscillators. Each oscillator can be reduced to a phase oscillator whose angular velocity on a circle is constant, except when it receives an input that resets (advances or delays) its phase on the circle. In a neural context, there is usually a threshold event, often the action potential or spike, which is used to demarcate the boundaries of a cycle. If an input shortens the cycle, the next spike occurs sooner than it otherwise would have, and so the next spike is advanced. Conversely, if the next spike occurs later than it otherwise would have, the spike is delayed.

The phase-resetting curve is sometimes presented as the response to a specific input. We have called this the general PRC. One example might be to perturb the oscillator underlying the circadian rhythm by exposing an animal to a period of light during its usual period of darkness; another example might be to stimulate a particular synaptic input or set of synaptic inputs to a neural oscillator. The ▶ [“Spike Time Response Curve”](#) is a way to plot the phase response to a specific input, that is, a spike in the presynaptic neuron, in a way that preserves information about time intervals. Phase-resetting theory is generally applied to neural circuits under a simplifying assumption; two common assumptions are that of pulsatile (brief) coupling or weak coupling. The entry on ▶ [“Pulse-Coupled Oscillators”](#) uses the information in the spike-time response curve (or the information in the general phase-resetting curve combined with the intrinsic period information) to predict the response of an oscillator to periodic forcing or mutual coupling, under the pulse-coupled

assumption that the effect of each input dissipates quickly compared to the cycle period.

A second use of the term phase-resetting curve is to represent the response of the oscillator to an infinitesimal input, in other words as a change in the period per unit of the input, called the infinitesimal PRC or iPRC. The entry on ► [“Phase Response Curve, Measurement of the Infinitesimal”](#) explains how to measure the infinitesimal phase response curve (iPRC). The iPRC is useful mostly in the context of the weak-coupling assumption, which assumes that the phase resetting due to two brief, sequential pulses summates linearly, and the phase resetting due to a single brief pulse rescales linearly with the height of the pulse. Thus, a complicated input like a postsynaptic current waveform can be conceptually broken up into a series of shifted and scaled pulses (Dirac delta functions). The entry on ► [“Weak Coupling Theory”](#) explains the connection between the iPRC and the general PRC. That is, if the coupling is sufficiently weak, the general phase resetting due to any arbitrary input waveform can be computed by summing the phase resetting due to each individual pulse: the timing of each pulse gives the phase, and the height of the pulse gives the scale factor for the resetting. This amounts to convolving the iPRC with the input waveform. Since the coupling is weak, the assumption is that the relative phases of the oscillators change very slowly. Weak coupling can be used to predict the synchronization tendencies of networks of oscillators. The entry on ► [“Phase Models, Noisy”](#) explains the effect of noise under the assumption of weak coupling.

Many factors, including the underlying bifurcation structure and the particular set of conductances expressed by the neuron, influence the PRC shape as described in the entry on ► [“Phase Response Curve, Measurement and Shape of General”](#). The influence of the underlying bifurcation structure described in that entry led to the classification of all PRCs with a single sign (all advances or all delays) as type 1 and those with both advances and delays as type 2. A completely separate, classification scheme into type 0 and type 1 PRCs is described in the entry on ► [“Phase Response Curve, Topology of”](#).

The two schemes are a potential source of confusion because of the similar terminology, but these schemes are unrelated. In the topology-based scheme, which was developed first, weak resetting leads to type 1 phase resetting, in which the phase immediately after an input can take on any value, but strong resetting leads to type 0 resetting in which only a limited set of phase values are allowed immediately after a strong input. This approach to classifying phase-resetting curves makes minimal assumptions, including pulse coupling, and is based on simple topological considerations.

In summary, phase response curves have been defined for both infinitesimal and general inputs. PRCs have been classified using separate, unrelated schemes based on bifurcation analysis or topology. Finally, PRCs have been used to analyze synchronization under assumptions of either weak or pulsatile coupling.

Retinal/Visual Interfaces (Models, Theory, Techniques): Overview

Nigel H. Lovell

Graduate School of Biomedical Engineering,
University of New South Wales, Sydney, NSW,
Australia

Synonyms

Artificial vision; Prosthetic vision; Visual neuroprosthesis

Definition

Retinal and visual interfaces encompass a range of approaches and technologies with the most common being that of a visual prosthesis, which is a subclass of sensory neuroprostheses. Such technologies can be used as a device therapeutic to restore some form of patterned vision to those suffering from profound vision impairment. Other approaches to vision restoration can also be included under the broad umbrella of a retinal/visual interface. These include optogenetic methods that use tissue engineering techniques to transfect remaining pathways in the visual system with photosensitive properties. Simulated prosthetic vision, methods to assess prosthetic vision, and computation models of the neural retina play important roles in increasing our

understanding of how such approaches function and can best be optimized.

Detailed Description

Vision is arguably the most feature rich and complex of the senses, with visual cues being critical to most activities of daily living. Vision impairment results in momentous personal and economic burdens to individuals and to society with global estimates of 285 million persons impacted (Pascolini and Mariotti 2012).

Figure 1 illustrates the human visual pathways. Pathology or trauma to various elements of the visual pathway results in vision impairment or profound vision loss. In retinal degenerative diseases, such as retinitis pigmentosa (RP) and age-related macular degeneration (AMD), the

Retinal/Visual Interfaces (Models, Theory, Techniques): Overview, Fig. 1 *Right panel:* an axial section of the human brain outlining a trace of the visual pathway from the retina to the primary visual cortex. *Other panels:*

possible intervention sites for artificial vision are categorized by retinal, optic nerve, and cortical placement locations. (Adapted from Lovell et al. 2010)

photoreceptors in the retina progressively die. In response to such diseases, there can be large-scale reorganization of the retina with substantial gliosis (Jones et al. 2003). Despite this, studies have shown that human retinal ganglion cells (RGCs) maintain their viability after the onset of these degenerative diseases, that the surviving retinal neurons are capable of being electrically stimulated (Humayun et al. 1996), and that rudimentary phosphene vision is achievable in humans with advanced retinal degeneration.

The etiology and/or site of insult to the visual pathway will dictate the range of possible target locations for a visual prosthesis (Guenther et al. 2012; Lovell et al. 2010). Possible sites for introducing a visual prosthesis include retinal (epiretinal (Humayun et al. 2012), subretinal (Zrenner et al. 2011; Palanker et al. 2005), suprachoroidal (Matteucci et al. 2013), trans-retinal (Fujikado et al. 2012)), optic nerve (Veraart et al. 2003), and cortical (Fernandez et al. 2005) locations (Fig. 1). In cases of trauma and diseases such as glaucoma, the RGCs can also be destroyed. As the RGC axonal processes form the optic nerve, in these cases electrical stimulation of visual pathways distal to the lateral geniculate nucleus (LGN) of the thalamus is ineffective.

In the case of retinal prostheses, to effectively replace vision with the same resolution as that of normally sighted humans would require an image capturing device to replace the function of the photoreceptor cells, of which there are approximately 125 million in each eye, converging to some one million RGCs. Current retinal devices, depending on placement and design, have electrode numbers from tens to several thousand at most.

The desired outcome is to have the electrode array placed in close proximity to the neural targets with the implanted components remaining securely fixed, even in the presence of rapid head and eye movements performed by the recipient. The device should maintain its position, integrity, and functionality for several decades of everyday usage, cause minimal injury, inflammation, or risk of infection to nearby tissue and cause minimal discomfort to the recipient. Also important in visual prosthesis design are aspects of size and battery life in the case of external componentry.

A typical vision prosthesis system comprises an external unit which using a camera and micro-processor performs the image capturing and processing and an implanted unit consisting of the microelectronic stimulator and the electrode array. Power and communication between the external and implanted units are normally facilitated by a transcutaneous radio-frequency (RF) link. The exceptions to this approach are typically sub-retinal devices that usually have photodiodes designed into the implantable component and thus have no need for an external camera.

Other more experimental approaches, in terms of readiness for human trials, are based around optogenetic techniques (Degenaar et al. 2009). This involves the use of viral transfection of rhodopsins to target various remaining cells in the visual pathway, making them photosensitive.

Common to all device therapies and target locations in the visual pathway are a list of challenges that must be overcome to improve efficacy and ensure device safety and longevity. These include maintaining a viable and stable neural interface over the long-term, device hermeticity and safe stimulation paradigms that allow concurrent stimulation at numerous electrode sites.

Software Tools for Modeling in Computational Neuroscience: Overview

Padraig Gleeson
Department of Neuroscience, Physiology and Pharmacology, University College London,
London, UK

Definition

A number of software tools have been made freely available to the neuroscience community to assist in building and analyzing biologically constrained

computational models of neuronal systems. This overview will present a number of the most widely used applications for model development in computational neuroscience.

Detailed Description

Modeling in computational neuroscience is becoming a crucial tool for understanding how experimentally observed properties of neural systems emerge from lower-level biophysical processes. In the same way that processing of information happens at multiple physical scales in the nervous system, software applications have been created which specialize in modeling different aspects of neurons and networks.

This overview deals primarily with simulators of spiking neural networks, but other applications for modeling at lower levels (e.g., for biochemical signaling networks or reaction–diffusion within spines or whole cells) or higher scale (e.g., models of cognitive processes) have also been developed. There is also a focus on freely available, open-source applications.

Simulators

Abstract Neuron Simulations

The emergent properties of networks are frequently studied using highly simplified neurons with complex network connectivity and synaptic dynamics. NEST (chapter ► [“NEST”](#)) is a widely used simulator for large neuronal models (e.g., 100,000 neurons and millions of synapses). It is highly optimized to run in a parallel computing environment. Another popular simulator of abstract neuronal networks is Brian (chapter ► [“Brian Spiking Neural Network Simulator”](#)), which is Python based and allows definition of new neuron and synapse models by writing the equations for their dynamics in a simple string-based format. Topographica (chapter ► [“Topographica”](#)) is a simulator which deals primarily with neural maps. It facilitates investigation of the transformation of information between layers of topographic maps as are found in sensory

and motor systems. XPP (<http://www.math.pitt.edu/~bard/xpp/xpp.html>) is a widely used tool for simulation and analysis of dynamical systems and has frequently been used to build and investigate neuronal systems. Nengo (<http://nengo.ca>) is a simulator for large-scale neuronal systems. It has been used for creating the Spaun (Semantic Pointer Architecture Unified Network) simulation (Eliasmith et al. 2012).

Conductance-Based, Multicompartmental Simulators

Single neurons possess a range of features enabling them to perform computational transformations on inputs, including complex morphological structures and a host of active membrane conductances. A number of simulators have been developed which allow researchers to construct neuron models at this level of detail and potentially link such cells together into networks inspired by anatomical circuits. NEURON (chapter ► “NEURON Simulation Environment”) is a general purpose neuronal simulation environment, which allows simulation of networks of neurons of varying levels of detail, from artificial/abstract cells to complex, morphologically detailed neurons. A key feature of NEURON is its extension language NMODL, which allows new ion channel and synapse models to be defined. An important recent addition to NEURON’s functionality has been the ability to run large scale network models across multiple processors. A number of other Python based applications have been created on top of NEURON, including NetPyNE (<http://netpyne.org>), which facilitates the creation of biophysically detailed network models, and LFPy (chapter ► “LFPy: Multimodal Modeling of Extracellular Neuronal Recordings in Python”), which allows the generation of higher level brain signals such as electroencephalography (EEG) and magnetoencephalography (MEG) from NEURON simulations.

GENESIS (► “GENESIS, The GENeral NEurol SIMulation System”) has also been widely used creating and analyzing detailed models of single cells and networks. MOOSE (► “MOOSE, the Multiscale Object-Oriented Simulation Environment”) was initially based on

GENESIS version 2 but has been further developed with a Python-based scripting interface, a new graphical user interface, and greater support for interacting with standardized modeling languages like SBML (► “Systems Biology Markup Language (SBML)”) and NeuroML (► “NeuroML”). PSICS (► “PSICS: The Parallel Stochastic Ion Channel Simulator”) can simulate multicompartmental, conductance-based cell models. Its particular strength is allowing efficient simulation of stochastic ion channels using a kinetic scheme-based approach.

Reaction–Diffusion Modeling

Modeling of the diffusion and reaction of biochemical substances in complex 3D structures can be useful for helping to understand the physical processes by which inputs are transformed in neurites and at synapses. Some of the applications available to create such models include MCell (MCell), STEPS (► “STEPS: STochastic Engine for Pathway Simulation”), and NeuroRD (► “Stochastic Simulators”). The NEURON simulator has also recently added support for reaction–diffusion simulations (McDougal et al. 2013).

Interoperability Frameworks

A diversity of simulation tools is beneficial from the point of view of offering greater choice to users and encouraging diverse approaches to neuronal simulation. There are a number of initiatives which aim to make it easier to use computational models across these simulators. PyNN (► “PyNN: A Python API for Neural Network Modelling”) is a Python library for building neuronal networks, which was inspired by an increasing number of neuronal simulators using the Python language as a scripting interface. A neuronal network can be created using PyNN and then can be simulated on (and the behavior compared across) multiple simulators. NeuroML (► “NeuroML”) is an XML-based language for describing models in computational neuroscience. This has been mainly used to encode 3D networks of multicompartmental, conductance-based neurons, but the recently developed version 2.0

increases its scope to more abstract neuron models. NineML (<http://incf.github.io/nineml-spec>) is another initiative to create an XML language for describing spiking neural networks. neuroConstruct (► [“neuroConstruct”](#)) is a graphical application which allows the construction of complex 3D networks of biophysically detailed neurons. Simulation scripts can then be automatically generated to execute the model in different simulation environments.

Neuronal Morphology Databasing and Generation

Many modeling studies use detailed neuronal morphologies to examine how information is processed and transformed by single neurons, through active membrane conductances and integration of synaptic input. Neuromorpho.Org (► [“NeuroMorpho.org”](#)) is the primary resource for obtaining neuronal morphologies which have been digitally reconstructed. It has contributions from many labs worldwide and covers a wide range of species and neuron types.

Detailed neuronal morphologies can also be automatically generated, based on data obtained from real neurons, for use in neuronal simulations. TREES Toolbox (► [“TREES Toolbox: Code for Neuronal Branching”](#)), CX3D (► [“Cx3D: Cortex Simulation in 3D”](#)) and NeuGen (<http://atlas.gcsc.uni-frankfurt.de/~neugen>) are just some of the applications which can be used for this purpose. More details on initiatives for generating artificial neurons which could be used in neuronal simulations can be found in the entry ► [“Synthetic Neuronal Circuits/Networks.”](#)

Useful Resources

Other useful resources where models, experimental data, and other software tools for computational neuroscience can be obtained include:

- ModelDB (► [“ModelDB”](#)): an archive of simulation scripts for published models in the format originally used by the model developers.

- Open Source Brain (► [“Open Source Brain”](#)): a resource for sharing and collaboratively developing neuronal models. Models reside in open-source repositories, and reusing, modifying, and converting the models to standardized formats such as NeuroML and PyNN are actively encouraged.
- Channelpedia (<http://channelpedia.epfl.ch>) is a resource developed by the Blue Brain Project which provides structured information on ion channels, and many of its entries have downloadable computational models of the channels.
- NeuroElectro (► [“NeuroElectro Project”](#)) provides structured information on electrophysiological properties of neurons obtained from the literature.
- NeuralEnsemble (<http://neuralensemble.org>) is a resource which aims to promote open, collaborative software development in computational neuroscience and hosts a number of related software packages (e.g., Brian and PyNN).

Other Software for Neuronal Simulation

Population-Based Modeling

While most of the simulation packages mentioned already use spiking neuron models, a significant amount of modeling work takes place in computational neuroscience using population-based models and mean-field approaches to model large-scale cognitive processes. Examples of software packages which allow this type of modeling are MIIND (► [“MIIND: A Population-Level Neural Simulator Incorporating Stochastic Point Neuron Models”](#)), a simulator for high-level population based modeling, and The Virtual Brain (► [“The Virtual Brain \(TVB\): Simulation Environment for Large-Scale Brain Networks”](#)), which provides a simulator and a web-based interface for constructing neural population models.

Hardware-Based Modeling Solutions

In addition to software-based neuronal simulators, many groups are investigating hardware-based

solutions to enable faster and larger-scale neuronal simulations. Many of these use off-the-shelf hardware like Graphics Processing Units (GPUs), for example, NeMo (<http://nemosim.sourceforge.net>) and GeNN (<http://genn-team.github.io/genn>), but other initiatives are developing new hardware, customized to simulate large-scale neuronal networks, for example, SpiNNaker (<http://apt.cs.man.ac.uk/projects/SpiNNaker>).

Systems Biology/Bioinformatics Tools

The Systems Biology community has been actively developing applications and model description languages in recent years to facilitate building and exchanging models of biochemical reactions, signaling pathways, and gene regulatory networks. SBML (► “[Systems Biology Markup Language \(SBML\)](#)”) and CellML (► “[CellML](#)”) are two widely used standards in this area, and many models in these formats, including neuronal models, can be obtained from the BioModels database (► “[BioModels Database: A Public Repository for Sharing Models of Biological Processes](#)”) and the CellML Model Repository (<http://models.cellml.org>).

Conclusions

The development of tools for modeling in computational neuroscience is a dynamic field. The overview here has no doubt left out a number of simulators and applications, which would be of use to the wider community. The author encourages developers to get in contact with details of their work for inclusion in future versions of this entry.

Somatosensory System: Overview

Sliman J. Bensmaïa

Department of Organismal Biology and Anatomy,
University of Chicago, Chicago, IL, USA

Detailed Description

Somatosensation includes multiple senses: pain (nociception), temperature (thermoreception), touch, and the sense of our limb position in space (proprioception). Each submodality of somatosensation relies on different types of receptors embedded in the skin, muscle, and joints and involves different structures in the spinal cord and in the brain.

Pain

Pain is arguably one of the most vital senses as it signals when our body is liable to being damaged. There are many different types of receptors in the skin that signal a potentially harmful stimulus. Some receptors respond to intense mechanical deformations of the skin, others to extreme temperatures, and still others to different kinds of chemicals. Pain comprises a sensory discriminative component, which provides information about the location, duration, intensity, and quality of the pain; an affective one, which signals its unpleasantness; and a cognitive-evaluative one, which is associated with cognitive variables such as attention, which can modulate the sensory experience.

Thermoreception

Our ability to sense whether an object is warm or cold relies on two types of thermoreceptive fibers – so-called “cold” and “warm” fibers – embedded in the skin. As their names suggest, “cold” fibers are activated when the skin is cooled

and “warm” fibers are activated when the skin is warmed. In contrast to thermosensitive nociceptive fibers, which respond at extreme temperatures, thermoreceptive fibers only respond at intermediate, non-noxious temperatures (with the exception of the paradoxical response of some cold fibers to high temperatures).

Touch

The sense of touch plays a critical role in our ability to grasp and manipulate objects. Indeed, cutaneous signals provide information about the forces we exert on objects and whether these are slipping from our grasp. Without these signals, we would routinely crush or drop objects. Touch also plays an important role in emotional communication: We touch the people we care about and wish to be touched by them. Finally, our sense of touch plays a key role in embodiment, making our body feel as a part of us.

The skin is innervated by several types of mechanoreceptive afferents, each of which conveys different information about skin deformations (link: sensory innervation of the skin) and conveys different types of information about events impinging upon the skin. Merkel cells convey information about the shape of objects grasped in the hand (link: cutaneous mechanoreceptive afferents: neural coding of shape), Meissner corpuscles about motion of objects across the skin, and Pacinian corpuscles about surface texture (link: cutaneous mechanoreceptive afferents: neural coding of texture). Afferents produce highly repeatable and temporally patterned responses to skin stimulation (link: somatosensory neurons: spike timing), and models have been developed that predict with high accuracy the responses of somatosensory neurons to spatiotemporal skin deformations (link: mechanotransduction: models).

When we palpate an object, we obtain information about its shape (link: somatosensory cortex: neural coding of shape), its texture (link: cutaneous mechanoreceptive afferents: neural

coding of texture), and its motion across the skin (link: somatosensory cortex: neural coding of motion).

Proprioception

Proprioception (link: proprioception) plays a critical role in guiding motor behavior. Individuals with intact motor systems but compromised proprioception have difficulty planning and executing movements, almost as if they had a motor impairment. Proprioception, like touch, is also important for our sense of embodiment.

There are several types of proprioceptive receptors, located in muscles, in the skin, and in joint capsules. Two types of muscle proprioceptors, muscle spindles and Golgi tendon organs, are thought to be the primary contributors to proprioception. One population of receptors in the skin is sensitive to skin stretch and can convey information about joint angle. Another type of proprioceptor, the joint capsule receptor, fires at the extreme ends of the joint’s range and may be involved in preventing overextension of the joint.

Proprioceptive and cutaneous signals are then processed in the dorsal column nuclei, then in the ventroposterior lateral nucleus in the thalamus, and then in primary and secondary somatosensory cortices (link: somatosensory cortex: organization).

Spectral Methods in Neural Data Analysis: Overview

Steven L. Bressler

Cognitive Neurodynamics Laboratory, Center for Complex Systems and Brain Sciences,
Department of Psychology, Florida Atlantic University, Boca Raton, FL, USA

Detailed Description

Spectral analysis is a powerful and widely used approach to the study of time series data (Warner 1998; Bloomfield 2000). It provides a useful complement to other types of analysis in computational neuroscience. Spectral analysis refers to a host of techniques relating to transformed time series in the frequency domain. A spectral representation of a time series is a function of frequency, where frequency is expressed in units of cycles per second, or hertz (Hz). Although spectral analysis is applicable to deterministic time functions, neural data is typically stochastic and thus requires statistical spectral analysis (Brillinger 2001; Bendat and Piersol 2010). Neural data types that are subjected to spectral analysis commonly include continuous time series such as the electroencephalogram (EEG), magnetoencephalogram (MEG), electrocorticogram (ECoG), and local field potential (LFP) but may also include point process time series such as single-unit and multiunit spiking activity (Glaser and Ruchkin 1976; Dumermuth and Molinari 1987; Hesselmann 1991).

Spectral methods in neural data analysis provide a frequency-based representation of neural time series data. They may be used to identify discrete, narrowband oscillations in time series or to decompose a broadband time series into frequency-specific components. Spectral methods are also employed in the frequency-based analysis of neural data arrayed in space rather than time (see ► “Spatial Spectral Analysis”). Spatial spectra are representations of spatial

data, and spatial frequency is expressed in units of cycles per unit distance.

The traditional approach to spectral analysis is based on the pioneering work of Joseph Fourier (1768–1830), the French mathematician who is credited with having first introduced the representation of a mathematical function as a sum of trigonometric functions. Nowadays, Fourier methods play a major role in a multitude of applications in mathematics, science, and engineering. Fourier analysis refers to the linear decomposition of a function into elemental trigonometric basis functions, whereas Fourier synthesis is the operation of rebuilding the original function from the component basis functions. Although functions subjected to Fourier analysis are often continuous and potentially infinite in length, they may also be discrete and finite in length. The wide availability of methods for Fourier analysis of digitized finite-length time series on digital computers has made spectral data analysis practical, rapid, and inexpensive (Marple 1987). As a result, spectral analysis of neural data has become increasingly popular in modern times, with a growing list of applications in theoretical, experimental, and clinical neuroscience.

Fourier analysis of a time series assigns values of amplitude and (absolute) phase to the trigonometric basis functions (sines and cosines) of the decomposition. For univariate time series, that is, from a single recording channel, Fourier analysis specifies a range of frequencies of the component basis functions, along with amplitude (or power, squared amplitude) and phase values for each frequency component. This (polar) representation in terms of amplitude and phase has an equivalent (Cartesian) representation in terms of the real and imaginary components of a complex quantity. The simplicity, symmetry, and facility of use of the complex Cartesian representation make complex algebra a useful mathematical tool in spectral analysis. However, complex algebra is not necessary. The polar and complex Cartesian representations are equivalent in providing a complete description of time series data, and Fourier synthesis can reconstruct the time series from either one.

Fourier analysis is often used to quantify interdependency relations between time series that are derived from different sources (see ► [“Spectral Interdependency Methods”](#)). Frequency-based interdependency measures may be derived from the complex-valued cross-spectrum. The cross-spectrum yields two important real-valued spectra. First is the relative phase (i.e., difference in phase) spectrum, given by the arctan of the ratio of imaginary to real components of the cross-spectrum. Second is the normalized modulus of the cross-spectrum, the coherence spectrum, which is the frequency domain equivalent of the time domain cross-correlation function. The relative phase spectrum reflects the mean, and the coherence spectrum reflects the variance, of the distribution of relative phase values of two time series. Coherence is roughly equivalent to the phase-locking value, defined as one minus the circular variance of relative phase, in that they both reflect relative phase variation. The difference is that coherence additionally reflects (to a lesser degree) amplitude covariation. Spectral methods are used to examine neural interdependency relations between continuous signals (e.g., between LFPs), or discrete signals (e.g., spiking activities), or between continuous and discrete signals (e.g., spike-field coherence).

Neural time series data are commonly multivariate, being derived from multiple sources, and their spectral analysis often involves the assessment of pairwise interdependency relations in the frequency domain. Some interdependency relations between time series are directional, meaning that the interdependency is directed from one time series to another. Directed spectral methods quantify directed interdependency in the frequency domain (see ► [“Directed Spectral Methods”](#)).

Because neural time series data commonly evolve over time, time-frequency, or spectrographic, representations are often useful (see ► [“Time-Frequency Analysis of Analog Neural Signals”](#)). This type of representation, which allows one to independently examine the temporal evolution of different frequency components, may be used to track the time-frequency evolution of a range of time-varying neural processes, including sleep, sensory, motor, and cognitive processing.

Spectrographic representations of the electroencephalogram (EEG) are heavily used in neuropharmacology to assess the actions of neuroactive drugs. A variety of different time-frequency methods, such as the short-time Fourier transform, Wigner-Ville distribution, Cohen’s class distribution, or wavelet transform (see ► [“Wavelet Analysis”](#)), have been applied in neural data analysis.

One important application of spectral methods in neural data analysis is filtering, the transformation of neural time series by the selection of certain frequency components and the exclusion of others (see ► [“Digital Filtering”](#)). Digital filtering, which refers to filtering operations performed on discretely sampled data in a digital computer, has the advantage of allowing data at both past and future time points to be used in determining the filtered value of a current time point, unlike analog filtering, where the filtering operation depends only on past time points. Although digital filtering may be performed in the time domain, it is more easily performed in the frequency domain by the selection of a range of frequencies (the passband) and exclusion of another range (the stopband). Data smoothing is an important operation in neural data analysis that is accomplished by digital (low-pass) filtering. Digital filtering is also used to separate spike and field signals recorded from a common microelectrode.

Neural time series are rarely deterministic, where each time series value is exactly determined by past values. For this reason, statistical spectral methods are usually required for neural time series analysis (Jenkins and Watts 1968; Percival and Walden 1993). Statistical spectral analysis considers time series data to be generated by stationary stochastic (random) processes, and the various spectral quantities are treated as data-derived statistical estimates of unknown population variables, rather than as deterministic quantities. Unlike non-parametric spectral analysis, which computes spectra directly from time series data by Fourier analysis, parametric spectral analysis is an approach that derives spectral quantities from a statistical model of the time series (see ► [“Parametric Spectral Analysis”](#)). In the model, the variable at a particular time is expressed by statistical relations with variables from past times. The

parametric model is typically autoregressive, meaning that each time series value is modeled as a weighted sum of past values (the weights being considered as the parameters of the model) (Kay 1988; Chatfield 2004). Although parametric models may be nonlinear, those used in neuroscience are typically linear because neural time series are commonly locally linear. Parametric modeling has some distinct advantages in neural data analysis: It allows a precise time-frequency representation of time-varying neural time series (Ding et al. 2000), and it serves as a theoretically sound basis for directed spectral analysis (Ding et al. 2006).

Spectral methods of neural data analysis utilize frequency-based representations. Since rhythmic activity, mostly in time but also in space, is ubiquitous in neuroscience, frequency-based techniques are very important tools in computational neuroscience. Given that many good software options exist for performing spectral data analysis, these techniques are readily available to neuroscience researchers working with many different types of neural data.

Spike Train Analysis: Overview

Sonja Grün

Lab for Statistical Neuroscience, Institute of Neuroscience and Medicine (INM-6, INM-10) and Institute for Advanced Simulation (IAS-6), Research Centre Jülich, Jülich, Germany
Theoretical Systems Neurobiology, RWTH Aachen University, Aachen, Germany

Definition

A sequence of action potentials (“spike train”) is the output of an individual neuron and is the input

to receiving neurons. It is assumed that neurons interact by sending and receiving spikes. Therefore, simultaneously observed spike trains are analyzed for correlations to identify neuronal interactions. This section presents analysis approaches for various statistical aspects of spike trains.

Detailed Description

The brain is composed of billions of neurons, the elementary units of neuronal information processing. The neocortex, which is critical to most higher brain functions, is a highly complex network of neurons, each of which receives signals from thousands of other neurons and projects its own output via sequences of spikes (► [“Spike Train”](#)) to thousands of other neurons (Braitenberg and Schüz 2009). In order to observe neuronal activity in the active brain, a large variety of recording techniques are being employed, ranging from recordings of individual neurons (intra- or extracellularly) to recordings of neuronal populations on mesoscopic or macroscopic scales. Any particular choice of the recording technique reflects the hypothesis the researcher has in mind about the mechanisms of neuronal processing. The focus on spike recordings from individual neurons implies that one strives to understand the elementary units of neuronal processing. However, approaching the relationship of different signal types may provide a means of relating processing on different spatial scales (► [“Spike Triggered Average”](#)).

Early electrophysiological experiments were bound to record from single neurons only. The resulting insights are now the basis for the “classical” view of sensory coding: firing rates are modulated in a feed-forward hierarchy of processing steps. Signals from sensory epithelia are assumed to eventually converge to cortical detectors for certain combinations of stimulus features (► [“Neural Coding”](#)) or finally transferred to motor output. Specific percepts or motor actions would be represented by the elevated firing of a single nerve cell (► [“Estimation of Neuronal Firing Rate”](#)) or by changes of firing rates of groups

of neurons which can be assessed by different conceptual approaches (► [“Neuronal Population Vector,”](#) ► [“Population Encoding/Decoding,”](#) and ► [“State-Space Models for the Analysis of Neural Spike Train and Behavioral Data”](#)).

An alternative concept of neuronal processing by groups of neurons was suggested by Donald Hebb (1949) who first demonstrated the conceptual power of a brain theory based on cell assemblies. Inspired by Hebb and driven by more recent physiological and anatomical evidence in favor of a distributed network hypothesis, brain theorists constructed models that rely on groups of neurons, rather than single nerve cells, as the *functional* building blocks for representation and processing of information. Despite conceptual similarities, such concepts of neuronal cooperativity differ in their detailed assumptions with respect to the spatiotemporal organization of the neuronal activity. To understand the principles of coordinated neuronal activity and its spatiotemporal scales, it is obligatory to observe the activity of multiple single neurons simultaneously. Due to recent technological developments in recording methodology, this can regularly be done. Coordinated activity of neurons is only visible in correlations of their respective spike trains, which typically admit no simple interpretation in terms of fixed synaptic wiring diagrams. Rather, it became evident that the correlation dynamics apparent in time-resolved multiple-channel measurements reflect variable and context-dependent coalitions among neurons and groups of neurons. Thus, the analysis of simultaneously recorded spike trains allows us to relate concerted activity of ensembles of neurons to behavior and cognition. Different analysis approaches are thereby relevant to distinguish different or even complementary spatio-temporal scales based on methods ranging from pairwise analysis (► [“Spike Train Distance,”](#) ► [“Correlation Analysis of Parallel Spike Trains,”](#) and ► [“Joint Peri Stimulus Time Histogram \(JPSTH\)”](#)) to concepts for the analysis of multiple parallel processes (► [“Gravity Analysis of Parallel Spike Trains,”](#) ► [“Unitary Event Analysis,”](#) ► [“Information Geometry as Applied to Neural Spike Data,”](#) ► [“Spatial Temporal Spike Pattern Analysis,”](#) ► [“Statistical Evaluation of](#)

Spatio-Temporal Spike Patterns,” and ► “Generalized Linear Models for Point Process Analyses of Neural Spiking Activity”). The evaluation of significance (► “Significance Evaluation”) is a basic element in these analyses, in some cases based on nonparametric methods (► “Surrogate Data for Evaluation of Spike Correlation”). Analysis of parallel spike trains (Grün and Rotter 2010; Kass et al. 2014) is the logical next step to improve our understanding of the neuronal mechanisms underlying information processing in the brain.

Spiking Network Models and Theory: Overview

Marc-Oliver Gewaltig
Blue Brain Project, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Definition

Spiking neuronal networks are a type of neural network model where the neurons interact by sending and receiving the so-called spikes, short pulses that are only defined by their time of occurrence. Biologically, spikes correspond to the action potentials of neurons.

Neuron models that produce spikes are called *spiking neuron models*. Examples are the Integrate and Fire Models, Deterministic; the *Izhikevich model*; and the Hodgkin-Huxley Model.

The term spiking network was introduced to distinguish these models from formal neuron models which have graded activation functions.

Detailed Description

Historical Background

The first spiking neuron models were developed at the beginning of the twentieth century and focused on explaining the electrical behavior of isolated neurons. In 1907, Louis Lapicque proposed an electrical circuit model to describe the change in membrane potential after applying a current step. He assumed a fixed firing threshold to explain the occurrence of action potentials (Lapicque 1907; Tuckwell 1988). Lapicque’s model can therefore be seen as the first *integrate and fire model*. In 1936, Arthur Hill extended Lapicque’s model by adding an adaptive threshold (Hill 1936). These models are phenomenological

since they did not explain the biophysical mechanisms producing action potentials. In the 1950s Hodgkin and Huxley explained with a series of experiments that action potentials are caused by ionic currents which result from ion channels with voltage-dependent conductances (Hodgkin and Huxley 1952). But because of its simplicity, Lapicque's original threshold model is still used by experimental and theoretical neuroscientists.

Theoretical network models initially focused on explaining experimentally observed interspike interval distributions of individual neurons as well as the origin of the observed high variability of neuronal responses. Recent theoretical research mainly focuses on understanding low-rate spontaneous activity as well as multistability in the context of learning and memory.

Theoretical analysis of spiking neuronal networks is only possible if the network model is sufficiently simple. In recent years, computer simulations have become increasingly important to support and complement theoretical analysis, because they allow the inclusion of more biological detail and the analysis of heterogeneous network architectures.

Spiking Neuron Models

Theoretical network models typically resort to simplified neuron models, such as the leaky integrate and fire model (LIF), some variant of it, or more abstract models such as pulse-coupled oscillators.

All of these neuron models have in common that they interact by sending and receiving the so-called spikes which are abstractions of the action potentials produced by excitable cells such as neurons.

Spikes are temporal point events, characterized by their time of occurrence $\hat{t}$ and mathematically expressed by the Dirac delta function $\delta(t)$.

A sequence of spikes $S = \{\hat{t}^1, \hat{t}^2, \dots\}$ is called *spike train* and can then be written as

$$s(t) = \sum_k \delta(t - \hat{t}^k), \quad (1)$$

where the index k runs over all spikes in S .

Integrate and Fire Models

The leaky integrate and fire (LIF) model constitutes a whole class of models consisting of two parts. The first part consists of one or more differential equations, describing the subthreshold behavior of the neuron's membrane potential. The second part converts the continuous membrane potential into discrete spike events. Here we will present the LIF model in its most basic form and then discuss a number of common variations.

Subthreshold Dynamics

The subthreshold membrane potential V is described by the differential equation

$$\tau \frac{d}{dt} V(t) = V_0 - V(t) + RI(t) \quad (2)$$

where V_0 is the resting potential, τ the membrane time constant, and R the membrane resistance.

$I(t) = I_{\text{syn}}(t) + I_{\text{ext}}(t) + \dots$ is the total current across the cell membrane and comprises all external influences on the neuron, such as synaptic currents I_{syn} and externally applied currents I_{ext} .

Spike Generation

Spikes are generated, when the membrane potential V crosses a threshold value V_θ from below. The time of spike is then given by the relation

$$V(t') = V_\theta \text{ and } \frac{d}{dt} V(t') > 0 \quad (3)$$

In the following, we use t' to denote the times of endogenous spikes and $\hat{t}$ to denote input spikes from other neurons.

After a spike is generated, the membrane potential is reset to V_{reset} , a value which is often chosen to match the resting potential V_0 .

Immediately after a spike, neurons are unable to produce another spike for a short period of time t_r , called *refractory period*. Many models implement the refractory period by holding the membrane potential at its reset value, such that $V(t) = V_{\text{reset}}$ for $t \in (t', t' + t_r]$.

Threshold Adaptation

Many neurons adapt to sustained input by reducing their firing rate. In integrate and fire models,

this is often captured by a mechanism called *threshold adaptation*.

The spike threshold V_θ is then no longer constant, but increases with every spike by an amount a and decays back to its resting value θ with a time constant τ_θ :

$$\tau_\theta \frac{d}{dt} V_\theta = \theta - V_\theta + a \sum_k \delta(t - t'^k) \quad (4)$$

where the sum runs over all endogenous spikes t'^k of the neuron.

Synaptic Input

Synaptic input enters the membrane potential in the form of the synaptic current $I_{\text{syn}}(t)$. A presynaptic spike at time $\hat{t}$ causes a conductance change at the postsynaptic membrane, which in turn results in a postsynaptic current of the form

$$I_{\text{syn}}(t, V) = (E_{\text{syn}} - V) \cdot g_{\text{syn}}(t - \hat{t}) \quad (5)$$

where E_{syn} is the reversal potential of the synapse and $g_{\text{syn}}(t)$ the time course of the conductance change.

Many models implicitly assume that the synaptic conductance changes much faster than the membrane potential V . Then V in Eq. 5 can be treated as constant, and the synaptic current no longer depends on the membrane potential which greatly simplifies analytical and numerical analysis.

In recent years, the terms COBA and CUBA have become popular to distinguish the two cases. COBA refers to the original Eq. 5 and stands for *conductance based*, while CUBA stands for *current based* and refers to simplified synaptic currents of the form

$$I_{\text{syn}}(t) = \text{psc}(t - \hat{t}) \quad (6)$$

where the postsynaptic current $\text{psc}(t)$ is only a function of time (Vogels and Abbot 2005).

Since Eq. 2 is a linear differential equation with constant coefficients, its solution for arbitrary postsynaptic currents $\text{psc}(t)$ is given by

$$\text{psc}(t) = V_0 + \int_0^\infty H(t - s) \exp\left(\frac{-(t - s)}{\tau}\right) \cdot \text{psc}(s) ds \quad (7)$$

where $H(t)$ is the Heaviside step function and $\text{psc}(t)$ is the so-called postsynaptic potential.

In the case where the postsynaptic current is a delta function $\text{psc}(t) := \delta(t - \hat{t})$, Eq. 7 reduces to

$$\text{psc}(t) = V_0 + \exp\left(\frac{-(t - \hat{t})}{\tau}\right). \quad (8)$$

In response to a spike train $s(t)$, we obtain

$$\text{psc}(t) = V_0 + \sum_k H(t - \hat{t}^k) \exp\left(\frac{-(t - \hat{t}^k)}{\tau}\right). \quad (9)$$

Spike-Response Model

The spike-response model (SRM) is a generalization of the LIF model (Gerstner et al. 1996a; Gerstner and Kistler 2002). It exploits the linearity of Eq. 2 and expresses the membrane potential as convolution:

$$V(t) = \eta(t - \hat{t}) + \int_0^\infty k(t, t') I_{\text{syn}}(t - t') dt' \quad (10)$$

where $\eta(t - t')$ is a kernel that describes the action potential as well as the after hyperpolarization of the last spike of the neuron at $t = t'$. $k(t, \hat{t})$ is a kernel that describes the response of the membrane potential to a presynaptic spike at time $\hat{t}$. Like in the LIF model, a spike is generated when the membrane potential $V(t)$ crosses a threshold value V_θ from below.

For theoretical analysis of large spiking network, the spike-response model is more convenient than the original LIF model, since it captures the effects of incoming as well as self-generated action potentials in a closed mathematical form (Gerstner and Kistler 2002).

Stochastic Spike Generation and Escape Noise

For most neuron models with a deterministic spike threshold, it is also possible to use a stochastic spike generation mechanism by adding the so-called escape noise (Plesser and Gerstner 2000). This is done by relating the variable $V(t)$ to the probability density for observing an action potential in the

infinitesimal time interval $(t, t + \delta t]$ (Plesser and Gerstner 2000; Mensi et al. 2012). In this picture, the spike generation is a random point process with a conditional density function

$$\lambda(t|V, V_\theta) = \lambda_0 \exp\left(\frac{V(t) - V_\theta}{\Delta V}\right), \quad (11)$$

where λ_0 is a scaling factor with unit s^{-1} , V_θ is the firing threshold, and ΔV is a factor that determines the steepness of the exponential function and therefore also the sensitivity of the firing threshold to small fluctuations.

The spike-response model with escape noise belongs to the larger class of *generalized linear models* (GLM) which have recently been used successfully also in other areas of neuroscience (see, e.g., Pillow et al. (2008), Truccolo et al. (2011)).

Stochastic Models of Neural Activity

In many regions of the brain, neurons fire constantly at a low rate, even if they are not directly stimulated. In the cortex, this spontaneous activity is very irregular. Moreover, even if a cortical neuron in vitro or in vivo is stimulated repeatedly, its response will differ for each stimulus presentation.

One of the earliest approaches to explain this variability of neuronal firing is to consider the fluctuation of the membrane potential of a neuron, caused by randomly arriving spikes from the surrounding network. In the simplest case, each neuron in the surrounding network will fire at some constant rate v . The network, thus, generates a noisy *background activity* which then influences the firing probability of our neuron.

The number of excitatory and inhibitory spikes which arrive at neuron i during the interval $(0, t]$ can be written as

$$n_E(t) = \sum_{j \in E_i} \int_0^t s_j(t' - d) dt',$$

$$n_I(t) = \sum_{j \in I_i} \int_0^t s_j(t' - t) dt'$$

where E_i and I_i denote the sets of all excitatory and inhibitory neurons projecting to neuron i ,

respectively. The membrane potential of a neuron can then be written as (Stein 1965; Tuckwell 1988)

$$\frac{dV}{dt} = -\frac{1}{\tau}V + J_E \frac{dn_E}{dt} + J_I \frac{dn_I}{dt}. \quad (12)$$

For sufficiently large networks, we can assume that n_E and n_I are Poisson processes with rates v_E and v_I , respectively.

In the absence of a threshold, and for constant firing rates, the mean and variance of the membrane depolarization are (Tuckwell 1988; Stein 1965)

$$E[V] = \tau(J_E v_E + J_I v_I) \quad (13)$$

$$\text{Var}[V] = \frac{1}{2} \tau (J_E^2 v_E + J_I^2 v_I). \quad (14)$$

More generally, we can describe the randomly arriving spikes as a *shot noise* process (Papoulis and Pillai 2002). This allows us to compute the mean and variance of the resulting membrane potential as a function of the background firing rate $v(t)$ and the synaptic response kernel $\text{psp}(t)$. The mean membrane potential is then

$$E[V]_t = \int_0^{+\infty} v(t-s) \text{psp}(s) ds \quad (15)$$

with variance

$$\text{Var}[V]_t = \int_0^{+\infty} v(t-s) \text{psp}^2(s) ds \quad (16)$$

When an embedding into a cortical region is considered, random input comes from excitatory and inhibitory populations. Due to the linearity of the equations, the contributions from both populations superimpose, and the mean and variance of the combined membrane potential are given by

$$E[V]_t = E[V_E]_t + E[V_I]_t \quad (17)$$

and

$$\text{Var}[V]_t = \text{Var}[V_E]_t + \text{Var}[V_I]_t \quad (18)$$

respectively.

Connections

A network consists of a set of N neurons and their connections. In a connection between two neurons, the sending neuron is called *presynaptic* and the receiving neuron is called *postsynaptic*. We write the set of presynaptic neurons of neuron i as N_i .

Static Connections

In the simplest case, the synaptic current simply adds the spikes of all presynaptic cells:

$$I_{\text{syn},i}(t) = \sum_{j \in N_i} J_{ij} s_j(t - d_{ij}) \quad (19)$$

$$= \sum_{j \in N_i} J_{ij} \sum_{k=1} \delta(t - d_{ij} - \hat{t}_j^k) \quad (20)$$

where d_{ij} is the propagation delay between neuron j and neuron i and $\hat{t}_j^k$ the k th spike of neuron j . J_{ij} is the *weight* or *efficacy* of the connection between neurons j and i which is in many cases assumed to be constant.

Dale's Principle

Dale's principle states that the efferent synapses of a neuron are all of the same type. Thus, if one efferent synapse of a neuron is excitatory, we know that all other efferent synapses of this neuron will also be excitatory. The same applies to inhibition.

Dale's principle introduces correlations into the connectivity matrix of the network, which are visible in the eigenvalue distribution of the matrix in the complex plane (Rajan and Abbot 2006). Moreover, Dale's principle also affects the correlation structure of random spiking networks. In random networks without Dale's principle, correlations between neurons will vanish in the limit of infinitely large networks. In such networks, Dale's principle prevents the correlations from disappearing (Kriener et al. 2008).

Short-Term Plasticity

The weight of a connection can depend on the spike history of the presynaptic neuron such that the weight decreases or increases if several

presynaptic spikes arrive in short succession. These effects are called short-term depression (STD) and short-term facilitation (STF), respectively. Both can be described by a system of kinetic equations that model the depletion and replenishing of synaptic resources (Tsodyks et al. 1998, 2000).

Assume that there is a finite amount of resources available and that each spike uses a certain fraction of these resources which are then unavailable for a certain amount of time. Depleted resources are replenished at a constant rate D . The second factor in the model is the ability of a synapse to use its resources, expressed by a variable $u(t)$. In stochastic models of synaptic transmission, u corresponds to the release probability of a synaptic release site (Fuhrmann et al. 2002). If u is a constant, the synapse will be depressing. For facilitating synapses, u increases with each spike up to a maximum and decays at a constant rate F .

In the context of the STP literature, the maximal synaptic efficacy is usually denoted by A which corresponds to the synaptic weight J , used throughout the rest of this entry. The effective weight for the n th spike can then be expressed as

$$A_n = Au_n R_n \quad (21)$$

with initial values

$$u_i := U, \quad (22)$$

$$R_1 := 1. \quad (23)$$

u and R are then iteratively updated according to

$$u_{n+1} = U + u_n(1 - U) \exp\left(\frac{-\Delta t_n}{F}\right), \quad (24)$$

$$R_{n+1} = 1 + (R_n - R_n u_n - 1) \exp\left(\frac{-\Delta t_n}{D}\right), \quad (25)$$

where $\Delta t_n := \hat{t}^n - \hat{t}^{n-1}$.

The relation of the time constants D and F determines whether a synapse will be

depressing, facilitating, or a combination of the two. However, closer analysis of the equations as well as experimental results shows that the detailed behavior of dynamic synapses depends also on the spike frequency of the presynaptic neuron (Fuhrmann et al. 2002).

Dynamic synapses have a strong effect on the behavior of a network. Networks with facilitating synapses can show collective synchronization of all neurons, called population bursts (Tsodyks et al. 2000). By contrast, in networks where the facilitating and depressing synapses are distributed as indicated by experimental results, activity is more stable as the synapses exert some gain control on the network (Sussillo et al. 2007).

Short-term plasticity has also been linked to the persistence of network states with elevated firing rates. These are thought to play an important role in working memory (Mongillo et al. 2008).

Short-term plasticity is not related to Hebbian plasticity, since it depends only on the activity of the presynaptic neuron rather than on the activity of both the pre- and postsynaptic neurons.

Spike-Timing-Dependent Plasticity

Spike-timing-dependent plasticity (STDP) is a form of synaptic plasticity where the synaptic efficacy changes according to the relative timing of pre- and postsynaptic action potentials.

A typical experimental protocol for spike-timing-dependent plasticity involves two neurons with a synaptic connection. Action potentials are induced in both neurons in a defined temporal sequence by injecting current pulses. At the same time, the strength of the synaptic potential is measured in the postsynaptic neuron. This procedure is called *pairing*. After a number of pairings, each with the same timing relation between pre- and postsynaptic neurons, a change in the amplitude of the PSP can be observed. Systematic variation of the relative timing between pre- and postsynaptic action potentials then reveals that the change in PSP amplitude depends on the timing relation.

The classical results of Markram et al. (1997) and Bi and Poo (1998) show that potentiation is largest if the postsynaptic neuron spikes shortly after the presynaptic neuron, while the synapse became depressed if the postsynaptic neuron

fired shortly before the presynaptic neuron. This is captured by the following model (Gerstner et al. 1996b):

$$\Delta J_{ij} = \sum_{\hat{t}^i \in S_j} \sum_{\hat{t}^j \in S_i} W(\hat{t}^i - \hat{t}^j) \quad (26)$$

where the sums run over all pre- and postsynaptic spikes, respectively. $W(\Delta t)$ is the so-called learning window, with

$$W(\Delta t) = A_+ \exp\left(\frac{-\Delta t}{\tau_+}\right) \text{ for } \Delta t > 0, \quad (27)$$

$$W(\Delta t) = -A_- \exp\left(\frac{\Delta t}{\tau_-}\right) \text{ for } \Delta t < 0, \quad (28)$$

and

$$\Delta t := t_{\text{post}} - t_{\text{pre}}. \quad (29)$$

The learning window is modeled as an exponential function which scales the degree to which the weight changes, depending on the time interval Δt . If the spike of the presynaptic neuron precedes the spike of the postsynaptic neuron, Δt is positive and Eq. 27 will increase the weight W by a value that is largest for short and smallest for large intervals. If the postsynaptic neuron spikes first, Δt is negative and Eq. 28 will decrease W .

There are a number of variations to this model as well as a number of alternative models which incorporate hypothesized biophysical mechanisms, underlying STDP (Morrison et al. 2008; Sjöström and Gerstner 2010). But so far, the experimental evidence does not allow to identify one of the models as authoritative (Feldman 2012).

Spike-timing-dependent plasticity is a mechanism that acts in addition to the synaptic short-term plasticity, described in the previous section. To obtain the final synaptic efficacy which combines both short-term and spike-timing-dependent plasticity, we replace A in Eq. 21 with $J + \Delta J$:

$$A_n = u_n R_n (J + \Delta J) \quad (30)$$

where J is the equilibrium weight.

Network Topologies

In a spiking network, the weighted, directed graph of the connections defines the topology of the network. Common network topologies are feedforward networks, recurrent networks, and networks with spatial topologies.

Feedforward Networks

Feedforward networks can be broken down into disjunct groups or layers of neurons $G_1, G_2, \dots$ where each neuron in group G_i is only connected to neurons in group G_j with $j \geq i$.

The propagation of spiking activity in feedforward networks is directed and in the direction of ascending group numbers. As a result, the total number of spikes in feedforward networks is limited, and at any given time, only a fraction of the neurons are active (Griffith 1963).

Synfire Chains

Examples of feedforward networks are the complete *transmission line*, also known as *synfire chain* (Griffith 1963; Abeles 1991). It consists of l mutually exclusive groups G_i , with $1 \leq i, \leq G_l$, each containing w neurons. Each neuron in group i projects to a certain number of neurons in group $i + 1$, thus forming a chain of groups of neurons. If sufficiently many neurons in the first group fire near simultaneously, they will ignite the neurons in the second group and so on. The spikes of the first group will therefore travel along the chain until either the activity disperses or the chain comes to an end. Theoretically, this can be described by the so-called pulse packets, propagating from one group to the next (Diesmann et al. 1999). In the ideal case, that is, given a sufficient number of spikes with a sufficiently narrow temporal spread, the pulse packet will propagate unchanged from one group to the next. And due to the divergent-convergent connectivity, small deviations from this invariant shape are then automatically repaired. However, depending on the number of neurons in a group and the connections between the groups, the pulse packet may also win or lose spikes or change its temporal precision (Diesmann et al. 1999; Câteau and Fukai 2001).

Recurrent Networks

Networks with feedback connections are called *recurrent*. Recurrent networks are often random with mixed excitation and inhibition. In random networks with uniform connection probability, each neuron has an equal probability to be connected to another neuron. In other models, the connection probability between neurons i and j depends on their distance.

Neighborhood Preserving Topologies

Networks in which neurons have a well-defined position are called *topology networks*. In such networks, the connection probability of two neurons usually depends on their distance. For example, the closer two neurons are, the higher is their probability to be connected. The neuronal positions may correspond to the actual positions of the neurons within a brain region, but they may also correspond to positions in some abstract space, for example, the orientation angle of a visual stimulus or the direction of movement in a reaching task. Thus, neighboring locations in stimulus or response coordinates are mapped to neighboring neurons.

The simplest examples of topological networks are line or ring networks, where the neurons are aligned on a one-dimensional axis. If the two ends of the axis are connected back to each other, the line turns into a circle. This is useful for representing periodic coordinates such as orientation angle or simply to avoid boundary effects at the end of the line.

Models of visual processing often use two-dimensional sheets or layers of neurons. Here the coordinates can correspond to visual space, e.g., the center of the neuron's receptive field or cortical space, that is, the actual position of the neuron in the brain. To ameliorate processing at the boundaries of the sheet, the two pairs of opposing sides are often connected such that the rectangular sheet turns into a torus.

Typical models of visual processing will combine several sheets into a functional architecture (e.g., Masquelier and Thorpe 2007; Grossberg and Versace 2008). Topological networks can be feedforward, recurrent, or a combination of the two.

Network Dynamics

Spiking neural network models are an important tool to study the dynamics of cortical network activity and to understand physiologically observed phenomena such as spontaneous activity, neuronal synchronization, and network oscillations. These are macroscopic network phenomena which we call the *macro state* of the network. Each macro state usually comprises a large ensemble of *micro states*, defined by the individual states of all neurons and synapses.

Many macro states, observed in cortical networks, can be understood, using a simple network with randomly connected excitatory and inhibitory neurons (Brunel 2000). The model consists of three populations of neurons: one population of excitatory neurons, one population of inhibitory neurons, and a third population of excitatory neurons, representing the long-range input from other brain regions. The excitatory and inhibitory populations are mutually coupled, and both receive input from the background population. We can now study the activity patterns which emerge, depending on the ratio of inhibition to excitation and the strength of the background population.

If the amount of excitation and inhibition is roughly equal so that on average the respective synaptic currents cancel each other, we speak of a *balanced network*. In this regime, network activity is highly irregular, since spikes are generated by the difference in fluctuations of the excitatory and inhibitory currents (Tsodyks and Sejnowski 1995).

If all neurons fire independently of each other and their spike patterns are essentially random, we speak of *asynchronous-irregular* activity. This state is of particular interest, because it corresponds best to the state of low-rate spontaneous activity, observed in cortical networks.

Networks in the asynchronous-irregular state exhibit chaotic activity (van Vreeswijk and Sompolinsky 1996). Thus, even small perturbation such as adding or removing one spike will quickly result in a completely different micro state. Whether this critical dependence on the initial conditions is useful or detrimental for spike-based processing is still under debate (Izhikevich 2006; London et al. 2010).

If the neurons fire independently, but each at regular intervals, we speak of *asynchronous-regular activity*. In this state, each neuron oscillates at a different frequency, and occasionally, large parts of the network will fire synchronously. The intervals of these population events depend on the common multiples of the individual firing periods. It is also possible that all neurons fire at the same frequency, but out of phase. In this case, neurons will not be able to occasionally synchronize their spikes.

If all neurons fire synchronously with the same frequency, the network essentially oscillates and we speak of *synchronous-regular* activity. Oscillatory states are also of interest since they can serve as models for epileptic activity or for stimulus-evoked synchronization.

Theoretically, there is also a state of *synchronous-irregular* activity, a state where each neuron produces the same irregular spike train. Then the spikes of all neurons will occur in synchrony, but the intervals between the spikes will be irregular. However, this state is very unlikely to occur in random networks because it requires a well-chosen connectivity.

Spinal and Neuromechanical Integration: Overview

Matthew Tresch¹ and Devin L. Jindrich²

¹Department of Biomedical Engineering and Physical Medicine and Rehabilitation, Northwestern University, Evanston, IL, USA

²Department of Kinesiology, California State University, San Marcos, CA, USA

Detailed Description

To interact with the environment or other organisms, the nervous system must move. Whether it is a fundamental protective reflex, a stabilizing postural adjustment, a rapid prey strike, or an expressive dance gesture, the motor repertoire of an organism defines the nature of its environmental interactions. Structures in the periphery of the motor system, the musculoskeletal system and spinal cord, most directly mediate these

environmental interactions. The actions of central brain regions such as cortex, cerebellum, or basal ganglia all ultimately have to pass through these peripheral structures. Understanding the properties of these peripheral systems is therefore critical for our understanding of the neural control of movement.

How should we consider these peripheral components of the motor system? In one common perspective, these systems are problems that the CNS must overcome. In this perspective, the complex properties of muscles, limb mechanics, motor neurons, and spinal circuits require that central motor systems develop strategies that invert, bypass, or suppress these complexities. Complexity could therefore lead to greater complexity: evolutionary changes to the periphery could require the co-evolution of more complex mechanisms to maintain performance.

In an alternate perspective, peripheral systems might simplify for motor control. The complexities of spinal systems or nonlinear properties of the musculoskeletal system might reflect adaptations that allow simplified control by descending systems. For example, passive mechanics can be used to assist movements (Collins et al. 2005), muscle properties can contribute to stability (Nichols and Houk 1973), basic reflexes allow for rapid control (Loeb et al. 1999), and defining adaptive muscle coordination patterns can potentially simplify movement (Tresch and Jarc 2009). In this perspective, energetic costs associated with inefficient, complex control might lead to evolutionary adaptations that simplify control and neural processing.

These two perspectives are not mutually exclusive, and both emphasize the importance of understanding the contribution of peripheral systems to motor control and brain function. Entries in other sections of this Encyclopedia and the *Encyclopedia of Neuroscience* describe the basic physiological properties of muscles (see Heckman et al. 2009), motor units (see Burke 2009), reflexes (see Grey and Nielsen 2009), and pattern generating spinal networks (see ► [Vertebrate Pattern Generation: Overview](#)). The entries in this section

expand on those descriptions, characterizing how these systems function and how they interact with descending systems. Spinal interneuronal systems have been studied extensively for more than a century, and although much remains unknown about their role in behavior, these studies have provided basic information that can be used to guide computational studies of motor control (► [Spinal Cord, Integrated \(Non CPG\) Models of](#)). Proprioceptors provide the nervous system with information about body state – the position of the limb, the forces produced by muscles, and the interactions with the environment. Understanding how these state variables are encoded in the activity of proprioceptor afferents is critical in understanding what information the nervous system has access to when interpreting and interacting with the environment (► [“Proprioceptor Models”](#)). Although spinal systems are capable of a great deal of motor coordination on their own, including central pattern generators for basic protective reflexes and for locomotion, voluntary behaviors are accomplished by descending pathways from the brain including the cortex. How these systems interact with one another to produce movement, however, remains poorly understood. One central computational issue in these interactions is how information about task goals (e.g., the location of food to be grasped) is translated into motor commands (e.g., the muscle activations that result in movement of the arm and hand to the food) ([Coordinate Transformations, Role of Spinal Circuitry in](#)).

Ultimately motor control is the result of a single dynamic system including both the nervous system and body, coupled together through intrinsic sensory feedback also through dynamic interactions with the environment. Neuromechanics is the field of study that seeks to understand how these two systems work together to produce behavior. Entries in this section examine the neuromechanics of postural control ([Neuromechanics of Postural Control](#)), characterizing how neural and musculoskeletal systems interact to stabilize the body to maintain upright stance, and the neuromechanics of joint

coordination during locomotion ([Neuromechanics of Joint Coordination](#)), characterizing how task goals are accomplished through dynamic coordination of low level execution variables.

Spinal Interfaces: Overview

Jacob G. McPherson¹ and Michel Lemay²

¹Program in Physical Therapy and Department of Anesthesiology, Washington University School of Medicine, St. Louis, MO, USA

²Department of Bioengineering, Temple University, Philadelphia, PA, USA

Definition

Spinal interfaces have traditionally focused on electrical stimulation of spinal cord tissue (i.e., white matter axonal tracts and/or gray matter neurons) or associated spinal roots (see ► [“General Overview of Spinal Anatomy and Physiology Organization”](#) in this Encyclopedia). Spinal interface applications have primarily centered about restoration of function lost to neurological impairment and study of spinal neural circuitry (organization, basic functions). More recently, spinal interfaces are being developed to record neural activity from large populations of spinal neurons and to deliver pharmacological agents to specific regions of the spinal cord. These interfaces may also be capable of simultaneously stimulating spinal tissue. Emerging application areas of spinal interfaces include chronic monitoring of neural transmission to serve as a biomarker of pathology/recovery and so-called closed-loop stimulation protocols, in which delivery of spinal stimulation is contingent upon real-time detection of salient neural activity. This latter category is particularly useful for studying and promoting neural plasticity in spinal circuits.

Methodologies to record and/or modulate neural transmission in spinal tissue can be divided on the basis of applications (bladder, movement restoration, pain reduction, etc.), electrode technology employed (electrical, optical, etc.), electrode position (e.g., epidural, intradural, intraspinal), or a number of other characteristics. In this entry, spinal interface techniques are presented based on the degree of invasiveness, and the similar technological methods used to record from or stimulate the neural tissue are highlighted. In

increasing order of invasiveness, spinal interfaces can be divided into (1) transcutaneous (recording and stimulation), (3) epidural, (4) intradural or intrathecal, and (5) intraspinal.

Detailed Description

High-Density Surface Electromyography

Spinal alpha motoneurons have long been the only neuron in the human central nervous system from which it is possible to obtain direct recordings. This is because motoneuron action potentials occur in a one-to-one ratio with motor unit action potentials (MUAPs), which are discrete action potentials evident in muscle fibers that can be accessed via electromyography (i.e., recording muscle electrical activity, EMG). Because each MUAP waveform has unique spatiotemporal features and because each muscle fiber is innervated by only one motoneuron (together, a “motor unit”), neural firing patterns of individual motoneurons can be discriminated from one another based on the shape of a given MUAP. These firing patterns are referred to as spike trains. When EMG is used to discriminate individual motor units and/or spike trains, it can be considered a form of transcutaneous spinal interface.

Traditional approaches for recording MUAPs, and by extension for accessing spike trains of discrete motoneurons, have relied on percutaneous needle-style or fine-wire electrodes that penetrate the skin and anchor into the muscle fibers below (i.e., intramuscular EMG). In addition to its invasiveness, this technique results in an extremely low yield of detectable motor units (~2–5/muscle) and provides reliable information only during contractions of low force magnitude.

Over the last 5–10 years, however, a powerful new technology has emerged for accessing motoneuron spike trains: high-density surface EMG (HD-sEMG) decomposition (Del Vecchio et al. 2020). In this non-invasive technique, flexible skin-surface electrodes containing 10’s of electrically and spatially isolated recording channels (typically 64 or 128) are placed over a muscle of interest. Surface EMG activity is recorded

simultaneously from each channel. Subtle differences in the spatiotemporal and spectral characteristics of each channel are then exploited by advanced statistical signal processing techniques (e.g., blind-source separation algorithms, independent components analysis) to decompose the multichannel surface EMG activity into individual MUAP waveforms and spike trains. This approach enables access to entire populations of discrete motor units (to date, ranging from ~10 to 40/muscle), providing a remarkably detailed window into descending neural drive and spinal motor output and distinguishing HD-sEMG decomposition from the general overview of motor unit function afforded by traditional intramuscular EMG. HD-sEMG decomposition is also substantially more robust than intramuscular EMG during contractions of increasing force magnitude, enabling studies of human motor unit recruitment and rate modulation that were previously either inferential or, more often than not, infeasible.

While the potential applications of HD-sEMG decomposition are near limitless, early examples have included advanced myoelectric control of prostheses (Kapelner et al. 2019), pathological neural control of movement following neurologic injury (Miller et al. 2014), and spinal motor output in the decerebrate cat (Thompson et al. 2018).

Transcutaneous Stimulation

Transcutaneous spinal stimulation refers to the activation of spinal tissue through the skin. It is broadly categorized either as magnetic stimulation or electrical stimulation. In the case of magnetic transcutaneous spinal stimulation, a magnetic field induces ionic currents within the spinal tissue (see ► [“Paraspinal Magnetic and Transcutaneous Electrical Stimulation”](#) entry in this Encyclopedia). The basic methodology involves inducing depolarization via a time-varying magnetic field delivered transcutaneously by a coil applied to the skin surface. This approach is similar in concept to transcranial magnetic stimulation (TMS) used to probe cortical circuits. The principal applications of transcutaneous spinal magnetic stimulation have been for the initiation of locomotion following spinal cord injury or in Parkinsonian patients and for the treatment of pain

when stimulation is delivered over the dorsal columns (see ► [“Paraspinal Magnetic and Transcutaneous Electrical Stimulation”](#) entry in this Encyclopedia). Finite element model studies of the spinal cord indicate that the greatest site of activation is within the tracts due to the lower threshold of activation of myelinated fibers of the white matter versus the cells of the gray matter (see ► [“Finite Element Models of Transcutaneous Spinal Cord Stimulation”](#) entry in this Encyclopedia). Since activation is typically delivered dorsally, the largest site of depolarization typically involves posterior roots and dorsal columns, although the anterior motor roots are also hot spots of depolarization.

Transcutaneous *electrical* stimulation can be used to indirectly modulate neural transmission in spinal circuits. In this approach, skin-surface electrodes are placed dorsally over the relevant vertebrae and traditional, pulsatile electrical stimulation is delivered. Rather than passing current directly into the spinal cord, the electrical stimulation is used to modulate neural transmission in primary afferent nerve fibers providing sensory inputs to spinal circuits damaged or weakened by injury. Although rarely described as such, some variants of classical transcutaneous electrical nerve stimulation (TENS) for pain are examples of this approach. More recently, however, transcutaneous electrical spinal stimulation has been introduced as a possible means to aid locomotor and upper limb rehabilitation following spinal cord injury (Inanici et al. 2018). The efficacy of this approach has not been demonstrated in randomized controlled trials as yet, and efforts to characterize the neural mechanisms by which it exerts potential therapeutic effects are ongoing but remain incomplete (Benavides et al. 2020).

Transcutaneous electrical spinal stimulation can also be delivered as a form of direct current stimulation, referred to as spinal cord direct current stimulation or transcutaneous direct current spinal stimulation (sDCS, tDCSS). Its use for modulating neural transmission in spinal circuits has paralleled that of similar approaches for modulating neural transmission in the brain. In tDCSS, two adhesive skin surface electrodes are placed on either side of the abdomen, one ventrally and one

dorsally. These electrodes are connected to the anode and cathode of a constant current stimulator, which drives current between the two sites. Unlike traditional transcutaneous electrical stimulation approaches (above), in which current is delivered in discrete pulses or trains thereof, in tDCSS the current is continuous (i.e., non-pulsed). In this regard, it can be considered to polarize the neural tissue for a period of time. The potential applications of tDCSS and the mechanisms by which it modulates neural transmission remain a source of active research. However, tDCSS appears to modulate transmission in motor and sensory regions of the spinal cord, as well as primary motor and sensory cortices, in a polarity-dependent manner (Cogiamanian et al. 2008, Ahmed 2011, Song and Martin 2017). These effects are thought to be driven at least in part by facilitation of certain forms of *activity-independent* neural plasticity (Jankowska 2017). Given its modulatory capacity and relative lack of invasiveness, tDCSS may be useful for priming spinal circuits during rehabilitation interventions.

Epidural Stimulation

Epidural stimulation refers to electrical stimulation delivered via leads inserted within the vertebral canal but outside the dura. Surgery is involved, but no stimulating electrodes are actually placed within the central nervous system or in the cerebrospinal fluid (CSF). Epidural stimulation is currently employed in a number of applications. Sacral anterior root stimulation combined with posterior sacral rhizotomy has been used extensively to restore bladder and bowel continence and voiding following spinal cord injury (Brindley 1988). Although most electrodes are implanted intradurally around the sacral roots, epidural electrode leads are sometimes used to activate the anterior sacral roots (typically S2, S3, and S4) (Egon et al. 1998). The anterior root stimulator takes advantage of the different contraction and relaxation times of the sphincter and bladder muscles. While the muscle fibers that constitute the sphincter are mainly “fast-twitch” muscle fibers that fatigue easily and relax very quickly, the fibers that compose the detrusor muscles are “slow-twitch” fibers that contract

gradually and maintain force for a longer period of time. With intermittent short bursts of high-frequency electrical pulses to the sacral nerve roots, bladder and sphincter muscles contract, but while the sphincter relaxes rapidly at the end of each stimulus burst, the pressure in the bladder is still sufficiently high to produce urination. Activation of the S2–S4 roots with longer stimulus trains is used to obtain defecation in a number of patients. Variations of the basic principles are still employed today, although advances in our knowledge of urogenital anatomy and electrode design have led to more sophisticated stimulation schemes (see ► [“Methodologies for the Restoration of Bladder and Bowel Functions”](#) in this Encyclopedia).

Epidural stimulation has also been used extensively for the restoration of locomotion following spinal cord injury in various animal models and humans (see ► [“Epidural Stimulation”](#) entry in this Encyclopedia). In all species, stimulation is delivered over the dorsal columns with the most efficacious segments for initiating locomotion varying between species. The stimulus train is typically a low-frequency (40 Hz) train of pulses delivered continuously over the dorsal columns at lumbar levels to produce activation of the locomotor circuitry. The exact mechanisms of activation or even the neuronal composition of the locomotor centers remains unknown, but the technique has been used clinically to restore standing and some locomotor movements in individuals with complete motor paralysis below the level of injury when coupled with highly intensive physical therapy (Edgerton and Harkema 2011; Harkema et al. 2011, Wagner et al. 2018). In animal models, the technique has also been combined with intrathecal delivery of targeted therapeutics to further aid restoration of locomotion and for upper limb rehabilitation, although these areas have yet to be realized clinically (Musienko et al. 2011, Barra et al. 2018). Epidural stimulation has also been employed to facilitate the initiation of locomotion in Parkinsonian patients (Fuentes et al. (2010), also see ► [“Spinal Stimulation for Parkinson Treatment”](#) in this Encyclopedia).

Finally, epidural stimulation of the dorsal columns has been applied for the treatment of chronic

and intractable pain arising from conditions such as failed back surgery syndrome, phantom limb pain, spinal cord injury, diabetic neuropathy, and ischemic limb pain (Kumar et al. 1998; Ramasubbu et al. 2013, Chari et al. 2017). Stimulation is delivered through electrode leads placed over the dorsal columns in an attempt to provide analgesia for a number of various chronic pain conditions. Success rate in the long-term relief of pain is variable, ranging from about 20% to 80% (Kumar et al. 1998). Similar to epidural electrical stimulation for locomotor rehabilitation, the mechanisms of analgesia remain unclear. In more recent implementations, which use stimulation frequencies in the KHz range, it is thought that the stimulation blocks neural transmission in ascending pain pathways (Crosby et al. 2017, Linderroth and Foreman 2017).

For both locomotor and analgesic applications, epidural stimulation has faced two particular challenges in clinical translation: off-target effects and the duration of therapeutic benefits. Off-target effects frequently take the form of paresthesias, which range from mildly irritating to painful in their own right. In some individuals, these effects limit the time that stimulation can be tolerated. A benefit of newer KHz-range stimulation paradigms is that they may evoke fewer or less intense paresthesias, although the efficacy of these paradigms for locomotor rehabilitation has yet to be investigated (Crosby et al. 2017). Regarding the duration of effects, in studies to date the therapeutic benefits of epidural stimulation often diminish rapidly upon cessation of stimulation. This phenomenon is presumably related both to the relatively nonspecific delivery of current to the spinal cord and to the non-physiological and asynchronous stimulus waveforms used to modulate neural transmission. While more targeted stimulation approaches and closed-loop stimulation paradigms may address some of these drawbacks, they are not without their own barriers to clinical translation (see below and other entries in this section).

Intradural Stimulation

Next in order of increasing invasiveness is intradural or intrathecal stimulation. Here, leads

are placed within the dural sac itself. Surgical and infection risks increase with this approach, as the implant is now placed within the central nervous system space and CSF and the blood-brain barrier is breached. Dural closure remains a surgical difficulty. However, closer proximity to the spinal cord provides greater access to specific spinal structures, allowing stimulation to be delivered to particular roots. Thus, it is no surprise that the Brindley-Finetch (described in Epidural Stimulation above) sacral anterior root electrodes are mostly implanted intradurally over the divided (anterior separated from posterior) sacral roots to restore bladder and bowel functions.

Intraspinal Stimulation

Intraspinal microstimulation (ISMS) provides the greatest access to the spinal cord but is also the most invasive and thus riskiest stimulation technique in terms of the potential damage it may cause to the nervous system. Stimulation is delivered within the spinal cord, typically via microwires implanted within the white and gray matter, although new high-density microelectrode array and optogenetic techniques amenable to spinal cord applications are being developed (Alilain et al. 2008, Lu et al. 2017). A particular benefit of ISMS for rehabilitation purposes is that it preserves orderly, physiological recruitment of motor units based on Henneman's Size Principle and allows smooth grading of contraction magnitude. This is contrasted by the well-documented reversed recruitment order and ballistic contractions common to transcutaneous neuromuscular electrical stimulation (NMES) techniques. ISMS of motor pools also readily recruits groups of synergist muscles, which has fueled many advances in our basic science understanding of spinal physiology but also provides an opportunity to cohesively restore grouped movements via a single stimulation site (which is not possible with transcutaneous NMES).

Applications of ISMS have included direct activation of motor pools/motor units to cause muscle contractions that aid locomotion (Bamford and Mushahwar 2011), bladder and bowel functions (Pikov et al. 2007), and respiration (Sunshine et al. 2018) (see ► [“Intraspinal](#)

[Stimulation](#)” in this Encyclopedia). Emerging applications include the induction and study of neural plasticity – particularly spike-timing-dependent plasticity – for rehabilitation using closed-loop neural computer interface approaches (McPherson et al. 2015, and see ► [“Electrical Conditioning for Spike-Timing-Dependent Plasticity of Neural Circuits”](#) in this Encyclopedia). And while the invasiveness of ISMS has presented a conceptual barrier to widespread translation, multiple efforts are currently underway to achieve regulatory approval for ISMS electrodes in humans. One need look no farther than deep brain stimulation electrodes as an example of the potential clinical translational path for efficacious but invasive neuromodulatory therapies.

Electrode Technologies: Issues and Potential Solutions

The electrodes used to deliver stimulation to the spinal cord are for the most part similar to the ones used to deliver electrical stimulation to peripheral nerves and/or the brain. They include cuff electrodes that use metalized contacts (typically platinum) encapsulated within silicone or other materials. These electrodes are typically used to stimulate roots (Brindley-Finotech anterior root stimulator electrode, and see Xiao et al. 2012 for more advanced designs). Metal disk or lead wires are typically used to deliver stimulation epidurally, and microwires are used to deliver stimulation intraspinally. New electrodes being developed and tested in animal models aim to increase the number of contacts and stimulation sites which would allow for greater selectivity in the delivery of stimulation. These include electrode designs for intraspinal microstimulation (Snow et al. 2006) and multi-contact surface electrodes for epidural stimulation (Gad et al. 2013).

Intraspinal microstimulation remains one of the toughest applications as the stiff metal- or silicone-based electrode presents a mechanical impedance mismatch compared to the higher compliance of the spinal tissue, leading to tissue damage. In addition, the spinal cord glides substantially within the vertebral canal during

movements (Ranger et al. 2008), and the tension it produces in the cable attaching electrode to associated connector may cause further damage to the tissue unless the cable’s flexibility is sufficient to dissociate the motions of the vertebral canal and spinal cord. A promising approach to minimizing mismatches in tissue and electrode material impedances is the braided electrode design of the Giszter group (see ► [“Braided Electrodes”](#) entry in this Encyclopedia). By braiding extremely fine wires, a very high overall compliance electrode and cabling technology is produced that can be inserted within the spinal cord with the help of a removable cannula guide and produce minimal histological damage to the central nervous tissue after long-term implantation (Kim et al. 2013a). As part of recent translation efforts, Mushahwar and colleagues have also begun development of ISMS implants for humans, performing initial mechanical testing of the implants in porcine models (Toossi et al. 2017). Wireless stimulators may also offer freedom from the cable tethering problem and potentially dura resealing. Miniaturized stimulators can be implanted close to the neural target and controlled via wireless approaches (radio frequency, optical, or acoustic waves, etc.). The approach can have the benefits of a cable-free approach like the transcutaneous stimulators but will allow much more precise targeting of the stimulation delivery (see ► [“Wireless Microstimulators”](#) entry in this Encyclopedia).

Other stimulation techniques have been used experimentally to activate the spinal cord, but to date no clinical application of these techniques has been pursued. Bizzi and colleagues have used iontophoresis to deliver an excitatory neurotransmitter locally within the gray matter (Saltiel et al. 1998), but since electrodes are pulled glass micropipettes, applications are limited to cases where the spinal cord can be securely immobilized. More recently, cell soma-sized micropipes have been developed to deliver electrical stimulation while simultaneously recording neurotransmitter release (Schwerdt et al. 2018). Although their mechanical impedance is encouraging for spinal cord applications, they have yet to be rigorously tested for this application.

Optogenetic methods have also been used to activate spinal tissue in the rat animal model (see ► **“Intraspinal Stimulation”** entry in this Encyclopedia). Stimulation is usually achieved with delivery of light from the surface, but delivery of light deep into tissue is possible through pulled optic fibers inserted into neural tissue (Gradinaru et al. 2009, Lu et al. 2017) and the development of new miniaturized optoelectronics (Kim et al. 2013b, Montgomery et al. 2015, Samineni et al. 2017). While earlier generations of optical fibers suffered from the same mechanical impedance mismatch issues as their metal electrode counterparts, these newer optrodes represent a substantial improvement in flexibility and compliance.

Finally, infrared light from lasers has also been used to elicit action potentials in peripheral nerve and cochlea of small (rodents and guinea pig) animal models (Izzo et al. 2006; Wells et al. 2005a, b; Xia et al. 2014). The methodology is termed optical stimulation, and action potential initiation appears to be caused by the induction of thermal transient within the axons or neurons (Wells et al. 2007). Depth of penetration of the light is a limiting factor attempting to activate deep tissue, and to date the technology has not been used in the spinal cord. Optical stimulation methods offer the advantage of producing no electrical stimulation artifacts, which facilitates neural recordings and closed-loop configurations because the amplifiers and analog-to-digital converters used in recordings are no longer saturated by the large electrical signal generated by the stimulus pulses.

changes in the amount and timing of transmitter released. In addition, surrounding cells such as glia can influence the local synaptic dynamics in tripartite synapse. Neurotransmitters bind to postsynaptic receptors that may induce current to flow that changes the postsynaptic neurons membrane potential or initiates signaling pathways that affect various properties of the postsynaptic neuron.

Synaptic Dynamics: Overview

Patrick D. Roberts

Department of Biomedical Engineering,

Definition

Synaptic dynamics describes the time-dependent changes in synaptic currents that alter the strength of coupling between neurons. Various mechanisms, both pre- and postsynaptic, contribute to ongoing changes of synaptic currents and modulate the overall network activity. These mechanisms operate on various time scales (milliseconds to years) and can lead to immediate changes in neuronal activity, ongoing adaptation of neuronal responses to changing inputs, and long-term learning and memory.

Detailed Description

Connections between neurons form network circuitry, and these connections are not static, but change in amplitude and timing. When a spike reaches a presynaptic terminal, processes are initiated that result in release of neurotransmitters that diffuse across the synaptic cleft to reach the postsynaptic receptors. Changes in these release dynamics can lead to short-term or lasting

Fast Dynamics

Changes of synaptic currents following a single synaptic transmitter release event are usually on the time scale of milliseconds to second and controlled by the dynamics of postsynaptic receptors. These fast dynamics follow a time course determined by transmitter diffusion, conformational changes in postsynaptic receptors that allows current to flow through the receptor pore, or changes that result in triggering second messengers that modify membrane currents. The resulting current flow is characterized by a sharp rise followed by a slower decay as the receptors inactivate and neurotransmitters unbind. The resulting currents can either excite or inhibit the activity of the postsynaptic neuron, depending on the selectivity of membrane channels for specific ions.

Ionotropic receptors. Receptors that allow direct current flow through a pore are called ionotropic receptors (Eccles and McGeer 1979) and provide the fastest synaptic dynamics. Mathematical representations of a synaptic current, $I_s(t)$, can be represented by a conductance $g_s(t)$ that regulates current flow across the membrane (Gerstner and Kistler 2002; Koch 2004),

$$I_s(t) = g_s(t) \cdot (V(t) - E_s), \quad (1)$$

where $V(t)$ is the membrane potential and E_s is the reversal potential of the current. If E_s is greater than the membrane potential, then the synaptic excites the neuronal activity, and if E_s is less than the membrane potential, then the synapse inhibits the neuronal activity.

The time-dependent synaptic conductance may be based on double exponential functions (or similarly shaped functions for $t \geq 0$).

$$g_s(t) = g_s \left(-e^{-t/\tau_1} + e^{-t/\tau_2} \right) \quad (2)$$

where τ_1 is the onset time constant and τ_2 is the decay time constant. More detailed representations of changes in synaptic conductances are developed in kinetic models of channels.

Two important types of excitatory currents are mediated by AMPA glutamate receptor and *N*-methyl-d-aspartate (NMDA) receptors that are excitatory in most neurons and have time constants for a risetime of a few milliseconds. They differ in two respects, time constants and dependence on postsynaptic voltage, but are often colocalized at the same synaptic zones. AMPA receptors usually have a larger peak conductance and decay with a few milliseconds (Trussell et al. 1993). NMDA receptors have a longer decay (Jahr and Stevens 1990), and the peak current is dependent on the postsynaptic membrane potential. NMDA receptors pass calcium ions that can initiate signaling cascades that may have a secondary effect on synaptic dynamics on a longer time scale such as long-term plasticity (Collingridge and Bliss 1987; Lisman 1989). Another important current is mediated by gamma-aminobutyric acid (GABA) receptors and is usually inhibitory in adult neurons.

Metabotropic receptors. Receptors that trigger second messengers to modify membrane currents are called metabotropic receptors (Eccles and McGeer 1979). These receptors are typically slower in their effect on the membrane potential than ionotropic receptors and can result in secondary long-lasting effects on the excitability of neurons. They can also help to initiate signaling cascades that lead to long-term synaptic plasticity. Their fast dynamics are mediated through changes in membrane currents, such as potassium currents, and the effects on membrane excitability can be either excitatory or inhibitory depending on the type of metabotropic receptor. In the simplest mathematical representations of these receptors, the conductance can be represented by a double

exponential function (Eq. 2) with a long onset time constant (τ_1) of several milliseconds.

Short-Term Dynamics

The synaptic dynamics caused by a spike may be affected by the history of previous spikes due to short-term plasticity (Zucker and Regehr 2002; Blitz et al. 2004). If the second of two spikes has a larger postsynaptic current than the first spikes, then the plasticity is called facilitation, and if the second spike has a smaller postsynaptic current, then it is called short-term depression. The amount of facilitation and depression on further spikes in a series changes over time and may saturate and last up to several seconds. The duration of facilitation and depression may occur on different time scales leading to complex sequences of postsynaptic currents that could be unique to the pattern of spikes.

Both pre- and postsynaptic mechanisms can be responsible for short-term plasticity. An important presynaptic mechanism is based on the presynaptic probability of neurotransmitter release for each spike combined with the rate of replenishment of presynaptic vesicles containing neurotransmitters. If the probability of release is high, then synaptic zones may not yet be prepared for the next spike leading to a reduced peak synaptic current observed in short-term depression. In contrast, if the release probability is low, then the first spike may have helped to prime the release so that the release probability is higher for the second spike. This increased release probability at each synaptic zone leads to an increase in peak synaptic current observed in facilitation.

Long-Term Dynamics

Changes in synaptic currents that last longer than several minutes are called long-term plasticity. Several mechanisms, both pre- and postsynaptic, may be responsible for these lasting changes that may increase or decrease the strength of synaptic currents. Increases in synaptic currents are called long-term potentiation (LTP) (Bliss and Lomo

1973), and decreases are called long-term depression (LTD) (Dudek and Bear 1993). Long-term plasticity may be dependent on the activity of pre- and postsynaptic neurons, and when the relative differences of timing of spikes between the neurons determine whether the change is potentiation or depression, then it is referred to as spike-timing-dependent plasticity (STDP) (Abbott and Nelson 2000). The processes of long-term depression and potentiation are balanced by synaptic scaling that adjusts the global input to neurons to maintain stable activity. Long-term plasticity is believed to form the basis of learning and memory as learned sensory cues, and behaviors are encoded in the strengths of synapse in neural circuitry (Hebb 1949).

Central pattern generator; CPG; Neural oscillator;
Rhythm generators

Definition

Central pattern generators (CPGs) are neural networks that can produce organized rhythmic patterns in the absence of rhythmic sensory and descending inputs from other parts of the nervous system (Marder and Calabrese 1996).

Detailed Description

Vertebrate Central Pattern Generators

The central nervous systems of vertebrates contain many types of central pattern generators (CPGs) that generate and control various rhythmic movements. These CPGs control important functions, including different forms of locomotion, such as swimming, walking, running, and flying, and non-locomotor processes and behaviors, such as breathing, swallowing, chewing, mastication, scratching, whisking (in rodents), singing (in birds), etc. This overview focuses on computational models of locomotion and breathing in mammals, which are briefly discussed below. Other known models of vertebrate CPGs include CPGs controlling swimming in *Xenopus*

tadpoles (Wolf et al. 2009; ► [“Rhythm Generation in Young *Xenopus* Tadpoles”](#)), zebra fish (Hill et al. 2004; Knudsen et al. 2006), and lamprey (Grillner et al. 2007); CPGs controlling swimming and walking in salamander (Ijspeert 2001; ► [“Control of Aquatic and Terrestrial Gaits in Salamander”](#)); CPGs controlling locomotion and scratching in turtles (Hao et al. 2011; ► [“Control of Locomotion and Scratching in Turtles”](#)); CPGs responsible for rhythm generation in embryonic chick spinal cord (Tabak et al. 2001; ► [“Rhythm Generation in Embryonic Chick Spinal Cord”](#)); and others.

Locomotor CPG in Mammals

The *Half-Center* Concept of the Locomotor CPG
The ability of the spinal cord to generate coordinated locomotor-like rhythmic activity in the absence of rhythmic supraspinal and afferent inputs provides strong evidence for both the existence of locomotor CPGs in vertebrates including mammals and their location in the spinal cord (Grillner 1981; Rossignol 1986; Orlovsky et al. 1999; Stuart and Hultborn 2008; Guertin 2009). The first schematic of a locomotor CPG, called the “half-center” model, was proposed by Graham Brown (1914, see also Stuart and Hultborn 2008; Guertin 2009). This model consisted of two (flexor and extensor) half-centers that reciprocally inhibited each other. The mutual inhibitory interactions between the half-centers were mediated by corresponding inhibitory interneurons, which ensured that only one half-center could be active at a time. The activity of the currently active half-center reduced gradually because of some fatigue or adaptation mechanisms leading to the activation of the antagonistic half-center, inhibiting the currently active half-center, and switching the locomotor phase. It was suggested that the flexor and extensor half-centers project to and activate the flexor and extensor motoneurons, respectively. Studies on immobilized decerebrate cats demonstrated that continuous electrical stimulation of the midbrain locomotor region (MLR) can produce “fictive locomotion” – the rhythmic pattern of motoneuron activity characterized by alternating activation of flexor and extensor

motoneurons similar to that observed during normal locomotion in the intact animal (Rossignol 1986). Similar patterns of locomotor activity could be also produced by systemic administration of the noradrenergic precursor, L-DOPA (e.g., Jankowska et al. 1967a, b). The demonstrated possibility to produce either MLR-evoked or drug-evoked fictive locomotion in the cat spinal cord has provided strong evidence for the existence of locomotor CPGs in the mammalian spinal cord.

The Unit Burst Generators Concept

CPG half-center models can be theoretically analyzed and classified into categories such as intrinsic escape, intrinsic release, synaptic escape, and synaptic release depending on which half-center and which process associated with this half-center control the transitions between activity states (Wang and Rinzel 1992; Skinner et al. 1994; Ausborn et al. 2018b; ► [“Comparative Analysis of Half-Center Central Pattern Generators \(CPGs\)”](#)). At the same time, the classical half-center concept can only represent a simplified CPG organization and cannot reproduce and explain many features of the locomotor pattern observed in the mammalian spinal cord. Specifically, biological locomotor activity does not exhibit strictly alternating flexor and extensor activities (with all motoneurons clearly belonging to one of these two groups) as suggested by the classical half-center model. The real pattern is more complex and includes motoneuron pools (such as those controlling biarticular muscles) generating bursts during both the flexion and extension phases of the step cycle or during only a part of one phase. There are also noticeable differences in the timing of burst onset and/or offset between different flexor and/or between different extensor pools. To overcome these and other limitations of the classical half-center model, Grillner (1981) proposed a unit burst generator (UBG) concept suggesting the existence of several separate rhythmogenic modules (or unit burst generators) controlling each joint of the limb and interacting with each other as coupled neural oscillators. A simplified mathematical model of the mammalian locomotor CPG based on the

UBG concept was proposed and analyzed by Sherwood et al. (2011; ► [“Computational Analysis of Rodent Spinal CPG”](#)). Despite many obvious advantages, this model showed a very slow recovery after applied perturbations. The analysis of sub-networks of this CPG revealed that the endogenous bursting properties of coupled neurons dominated over the phasing and synchronization properties of the CPG network, leading to the slow phase resetting and rhythm stabilization in response to applied perturbations.

The Two-Level Model of the Locomotor CPG

An important extension of the classical half-center model was suggested based on the analysis of (a) spontaneous deletions (missing bursts) in the rhythmic motoneuron activities and (b) effects of afferent stimulations on the locomotor pattern during fictive locomotion in the cat (Rybak et al. 2006a, b; McCrea and Rybak 2007, 2008; ► [“Two-Level Model of Mammalian Locomotor CPG”](#)). This analysis led to the suggestion that the locomotor CPG has a two-level architecture with a separate top-level, half-center rhythm generator (RG) and a pattern formation network (PF). While the RG defines the locomotor frequency, the PF network is controlled by the RG and defines and coordinates the more complicated firing patterns of different motoneuron pools. The two-level model was able to reproduce a number of features of the locomotor pattern observed during cat locomotion, including phase maintenance of motoneuron activities following spontaneous deletions or brief stimulation of some afferents, which would be difficult or even impossible to explain in the framework of the classical half-center architecture (see ► [“Two-Level Model of Mammalian Locomotor CPG”](#)). Some aspects of supraspinal and afferent control of the two-level locomotor CPG were analyzed using computational modeling approaches (Rybak et al. 2006a; Markin et al. 2010; Spardy et al. 2011a, b).

One advantage of the two-level model is a possibility to perform independent control (by supraspinal and afferent inputs) of the step cycle duration (locomotor speed) at the RG level and the activity of motoneurons and motor synergies at the PF level. This CPG model was used in

several studies focused on the development of CPG-controlled legged robots (Chen et al. 2007; Maeda 2008; Amrollah and Henaff 2010).

Rhythmic Activity in Isolated Spinal Cord Preparations of Rodents

The mammalian locomotor CPG was also studied in vitro using isolated spinal cord preparations of rodents (Smith and Feldman 1987; ► “Locomotor Pattern Generation in the Rodent Spinal Cord”). The locomotor CPG in these preparations can be activated in several ways, including pharmacological manipulations [by using solutions with specific combinations of *N*-methyl-D-aspartate (NMDA) and serotonin], stimulations of sensory afferents or dorsal roots, and brainstem stimulation. The elicited motor output shows alternation of activity in the left and right ventral roots (e.g., left L2 and right L2) combined with alternation of ipsilateral flexor (L2) and extensor (L5) activities on each side of the cord. Significant progress in the understanding of functional and structural organization of spinal circuits has been achieved using special combinations of genetic, molecular, and developmental approaches. Several classes of spinal interneurons were defined in the embryonic and early postnatal spinal cord based on the dynamic expression pattern of transcription factors (Goulding 2009; Whelan 2010; Gosgnach 2011; Kiehn 2011; Dougherty and Ha 2019; ► “Locomotor Pattern Generation in the Rodent Spinal Cord”). The new genetic techniques allow visualization of identified neurons as well as manipulation of their activity and their selective elimination. Several classes of inhibitory (CINi) and excitatory (CINE) commissural interneurons (CINs) have been identified. The axons of these cells cross the midline, project to the opposite side of the cord, and mediate interactions between left and right circuits. The role of different CINs in locomotion has been identified by using transgenic mice with mutations in, or knockout (KO) of, specific genes resulting in various abnormal locomotor phenotypes (Kullander et al. 2003; Lanuza et al. 2004; Akay et al. 2006; Lundfald et al. 2007; Crone et al. 2008, 2009; Zhang et al. 2008; Zagoraïou et al. 2009; Rabe et al. 2009; Restrepo et al. 2011; Talpalar et al. 2013).

A two-level computational model of neural circuits in the spinal cord with left and right rhythm-generating populations interacting via inhibitory and excitatory CINs has been developed based on the analysis of spontaneous deletions in the isolated spinal cord preparation with rhythmic activity evoked by administration of NMDA and serotonin (Zhong et al. 2012; ► “Locomotor Pattern Generation in the Rodent Spinal Cord”) and further refined in subsequent studies (Rybak et al. 2013, 2015; Shevtsova et al. 2015; Shevtsova and Rybak 2016; Danner et al. 2016, 2017).

Modeling the Effects of Genetic Transformations on the Locomotor Pattern

A representative example of how genetic manipulations can change the phase relationships between ipsi- and contralateral neurons involved in control of locomotion in mice is based on the genetic ablation of special molecules involved in guidance of CIN axons, such as Netrin-1 and DCC. Also, the spinal cord contains glutamatergic interneurons with ipsilateral projections, whose axon guidance involves the EphA4 receptor. In *EphA4* knockout (KO) and *Netrin-1* KO mice, the normal left–right alternating pattern is replaced with a synchronized hopping gait, and the spinal cord of *DCC* KO mice exhibits uncoordinated left and right oscillations (Rabe et al. 2009; Restrepo et al. 2011; Rabe Bernhardt et al. 2012; Vallstedt and Kullander 2013). To investigate the effects of these genetic transformations, Rybak et al. (2013) developed a computational model of the spinal circuits containing the left and right rhythm-generating neuron populations (RGs), each with a subpopulation of EphA4-positive neurons, and the CINi and CINE populations mediating, respectively, mutual inhibition and mutual excitation between the left and right RGs. In the *EphA4* KO circuits, half of the axons of EphA4-positive cells crossed the midline and excited the contralateral RG neurons. In the *Netrin-1* KO model, the number of contralateral CINi projections was significantly reduced, while in the *DCC* KO model, the numbers of connections from both CINi and CINE were reduced. In the simulations performed, the models of *EphA4* and *Netrin-1* KO circuits showed switching from the left–right alternating

pattern to a synchronized hopping pattern, and the *DCC* KO network exhibited uncoordinated left–right activity. The model was able to reproduce multiple experimental data on the effects of above genetic transformations on the locomotor pattern, providing important insights into the organization of the spinal locomotor network and was later build upon by subsequent studies (Shevtsova et al. 2015; Danner et al. 2016, 2017; Ausborn et al. 2019).

Respiratory CPG in Mammals

Respiratory Pattern and Spatial Organization of the Respiratory CPG

The respiratory motor pattern observed during quiet breathing in mammals (“eupnea”) consists of three phases: inspiration (I), post-inspiration (post-I or E1), and late expiration (E2), which can be recognized in the integrated activity of the phrenic and cranial nerves. This pattern originates within a bilateral column of neurons, called the ventral respiratory column (VRC), located in the ventrolateral medulla and controlled by inputs from other medullary (retrotrapezoid nucleus, RTN, raphé, etc.) and pontine regions. The VRC includes several compartments arranged in the rostro-caudal direction: Bötzing Complex (BötC), pre-Bötzing Complex (pre-BötC), and rostral (rVRG) and caudal (cVRG) subregions of the ventral respiratory group (VRG). Respiratory neurons in these compartments are usually classified based on their firing pattern (e.g., decrementing, augmenting) and phase of activity relative to the breathing cycle, such as early inspiratory (early-I or I-DEC), i.e., inspiratory neurons with a decrementing discharge pattern; ramp-inspiratory (ramp-I or I-AUG), i.e., inspiratory neurons with an augmenting firing pattern; post-inspiratory neurons (post-I or E-DEC), i.e., neurons with a decrementing activity during expiration; augmenting or stage II expiratory (aug-E or E-AUG or E2), i.e., expiratory neurons with an augmenting pattern; and pre-inspiratory/inspiratory neurons (pre-I/I), i.e., the neurons whose activity starts before the onset of inspiration and continues throughout inspiration. The BötC, with predominately post-I and aug-E

neurons, is considered to be a major source of expiratory activity. The adjacent, more caudal pre-BötC contains neural circuits essential for generating inspiratory activity (Cohen 1979; Bianchi et al. 1995; Richter 1996; Smith et al. 2013).

Computational models of the respiratory network have been in development for several decades. Early computational models of the respiratory CPG focused on the network interactions between different types of respiratory neurons and did not consider intrinsic biophysical rhythmogenic properties of single respiratory neurons and their possible contribution to rhythmogenesis. Generation of the respiratory rhythm in these models was based on the half-center concept suggesting that the respiratory oscillations result from sequential phase switching resulting from the reciprocal inhibitory interactions between different types of respiratory neurons (Botros and Brace 1990; Duffin 1991; Ogilvie et al. 1992; Balis et al. 1994; Rybak et al. 1997; reviewed by Lindsey et al. 2012).

The Pre-Bötzing Complex and Rhythm Generation In Vitro

A fundamentally distinct concept of respiratory rhythm generation was derived from neonatal in vitro studies. An important discovery has been that a subregion of the VRC, called the pre-Bötzing Complex, contains a population of excitatory interneurons that can intrinsically generate an inspiratory-like rhythm (Smith et al. 1991). This rhythm was shown to persist after blockade of synaptic inhibition, indicating that the pre-BötC may contain cells with intrinsic bursting properties. Butera et al. (1999a, b) developed and analyzed a series of computational models of bursting pacemaker neurons and populations of these neurons with mutual excitatory connections. In these models, the intrinsic bursting was based on a slowly inactivating persistent sodium current (I_{NaP}) as the essential burst-generating, inward cationic current. The rhythmic bursting cycle in these models was controlled by the slow kinetics of inactivation and recovery from inactivation of I_{NaP} . Simulations performed have shown that the excitatory synaptic

interactions coupled with I_{NaP} activation can readily synchronize cellular bursts and produce population bursting. Importantly, generation of this rhythm does not require inhibitory interactions, which can explain the persistence of the *in vitro* oscillations after inhibitory synaptic transmission was blocked. It was also shown that even a small fraction of intrinsically bursting cells (5–10%) can produce a synchronized bursting activity of the entire population. Moreover, synchronized population activity may occur even if none of the cells operate in the intrinsic bursting state. Elevation of tonic drive to the population reduces burst duration, increases burst frequency, and, finally, switches population activity from population bursting to a regime of sustained asynchronous activity (Butera et al. 1999a).

Network-Based Versus Pacemaker-Driven Mechanisms for Respiratory Rhythmogenesis and Hybrid Pacemaker–Network Models

The early network models were able to generate a realistic respiratory motor pattern and simulate various alterations of this pattern under different conditions. However, these models failed to reproduce some characteristic behaviors observed in the reduced *in vitro* preparations and, specifically, the maintenance of the respiratory rhythm following inhibition blockade. Alternatively, the pacemaker-based models, developed to fit to *in vitro* data, could not explain many respiratory behaviors observed *in vivo*, such as the Hering–Breuer and other respiratory reflexes as well as the independent control of the duration of each respiratory phase. Neither could these models reproduce apneusis, a well-known abnormal breathing pattern characterized by a significantly prolonged inspiration (up to several seconds) alternating with short expiratory intervals. Moreover, the rhythmic activity generated in the reduced *in vitro* preparations and reproduced by the pacemaker-driven models is characterized by a decrementing shape of inspiratory discharges that clearly differs from the augmenting shape of phrenic discharges generated during eupneic breathing *in vivo*; these discharges rather resemble the decrementing bursts observed during gasping.

The above contradictions between the network-based and the pacemaker-based concepts and models can be resolved by postulating that (i) the pre-BötC, while capable of intrinsic bursting when isolated and under some special conditions, is normally embedded in the larger brainstem respiratory network which makes its behavior dependent on its interactions with other brainstem structures and (ii) the respiratory rhythmogenesis is state dependent, and therefore the respiratory oscillations may be generated by either a network-based or pacemaker-driven mechanisms or their specific combinations depending on the conditions (Smith et al. 2000, 2007; Rybak et al. 2002, 2004, 2007; Lindsey et al. 2012; Smith et al. 2013; Koizumi et al. 2016; Ausborn et al. 2018a; ► “Computational Models of Mammalian Respiratory CPG”).

The Respiratory CPG and Spatial and Functional Hierarchy of Multiple Rhythmogenic Mechanisms

Significant progress in understanding of spatial and functional organization of the respiratory CPG in the mammalian brainstem has been achieved by using an arterially perfused *in situ* rat brainstem–spinal cord preparation (Paton 1996) and applying sequential rostral-to-caudal microtransections through the brainstem while recording cranial and spinal motor outflow to observe transformations of network behavior (Rybak et al. 2007; Smith et al. 2007). This approach revealed the existence of a rostral-to-caudal stacking of network building blocks serving distinct circuit functions, which are fully integrated in the intact system, but can be revealed when particular compartments are removed or under special metabolic conditions (hypoxia, hypercapnia). These studies revealed that sequential reduction of the network progressively reorganizes network dynamics, such that new rhythmogenic mechanisms emerge. Specifically, starting from a transection at the pontine–medullary junction, the normal three-phase respiratory pattern is transformed to a two-phase rhythmic pattern lacking the post-I phase. With more caudal transections made close to or at the rostral boundary of the

pre-BötC, the respiratory activity transforms to “one-phase” inspiratory oscillations originating within the pre-BötC, without critical involvement of phasic expiratory inhibition (Rybak et al. 2007; Smith et al. 2007). These results led to the conclusion that (i) generation of the normal three-phase rhythmic pattern requires the presence of the pons (i.e., excitatory drive from pontine neurons to the VRC); (ii) generation of the two-phase pattern is intrinsic to reciprocal inhibitory synaptic interactions between the BötC and the pre-BötC and may also involve the RTN to provide excitatory drive to generate stable behavior; and (iii) the one-phase inspiratory oscillations are generated within the pre-BötC and rely on intrinsic cellular mechanisms operating in the context of the pre-BötC excitatory network. These data allowed the conclusion that there is a spatial and dynamical hierarchy of interacting pontine, BötC and pre-BötC circuits, each of which controls different aspects of respiratory rhythm generation and pattern formation, which can be revealed as the network is progressively reduced. The expression of each rhythmogenic mechanism is state dependent and produces specific motor patterns likely to underpin distinct motor behaviors (Smith et al. 2007, 2013; ► “Computational Models of Mammalian Respiratory CPG”).

A minimal network configuration proposed to represent the above multiple rhythmic states and their transformations included (i) a mutually inhibitory circuit with a ringlike architecture composed of post-I and aug-E neurons of the BötC compartment and early-I neurons within the pre-BötC and (ii) a pre-BötC kernel of excitatory pre-I/I neurons, with intrinsic I_{NaP} -dependent bursting properties. The latter participate dynamically in the expiratory–inspiratory phase transition and generation of the inspiratory phase. The detailed description and computational model of this core network and the circuit elements participating in each rhythmic state can be found in a series of related publications (Rybak et al. 2007; Smith et al. 2007; Rubin et al. 2009b; for review see also Lindsey et al. 2012; Smith et al. 2013; ► “Computational Models of Mammalian Respiratory CPG”).

Respiratory Rhythm Generation and Coupled Oscillators

As described above, the respiratory CPG is considered to comprise several interacting populations of respiratory neurons located in the pre-BötC and BötC circuits within the VRC. A distinct site of neural oscillations was identified in vitro in the isolated neonatal rat brain stem–spinal cord preparation (Onimaru and Homma 1987, 2003; Onimaru et al. 1988). This additional oscillator, called the parafacial respiratory group (pFRG), seems to reside within, or overlap with, the RTN. It was also found that RTN/pFRG oscillations in vivo drive abdominal motor activity, expressing late-expiratory (late-E, or pre-inspiratory) bursts or biphasic discharges (with pre-I and post-I components) in the abdominal motor output when the system operates in the active (forced) expiration regime (Janczewski et al. 2002; Janczewski and Feldman 2006; Feldman and Del Negro 2006; Abdala et al. 2009). Several competing concepts concerning the physiological role of RTN/pFRG oscillations have been suggested, including the dual oscillator concept that considers the RTN/pFRG as an independent expiratory rhythm generator coupled with a distinct inspiratory rhythm generator in the pre-BötC (Janczewski and Feldman 2006). However, the exact physiological role of pFRG oscillations, the specific conditions for their emergence, and the nature and mechanisms of the interactions between the BötC/pre-BötC and RTN/pFRG oscillators are not yet known.

Molkov et al. (2010; ► “Coupled Oscillations in Neural Control of Breathing”) extended the previous respiratory CPG model (Rybak et al. 2007; Smith et al. 2007) to include the RTN/pFRG oscillator and consider interactions between the BötC/pre-BötC and RTN/pFRG oscillators. The extended model incorporates an additional late-E population in the RTN/pFRG compartment, representing a source of late-E oscillatory activity. In the proposed model, under normal metabolic conditions, the RTN/pFRG oscillator is inhibited by the BötC/pre-BötC circuits, and the late-E oscillations can be only released by either hypercapnia-evoked activation of RTN/pFRG or by hypoxia-dependent

suppression of RTN/pFRG inhibition by BötC/pre-BötC. The proposed interactions between the BötC/pre-BötC and RTN/pFRG oscillators allow the model to reproduce several experimentally observed behaviors, including *quantal acceleration* of abdominal late-E oscillations with progressive hypercapnia and *quantal slowing* of phrenic activity with progressive suppression of pre-BötC excitability, as well as to predict a release of late-E oscillations by disinhibition of RTN/pFRG under normal conditions (Molkov et al. 2010; ► “Coupled Oscillations in Neural Control of Breathing”). Rubin et al. (2011) performed thorough analysis of the reduced model and explained the regimes of quantal acceleration and quantal slowing in terms of synchronization of the BötC/pre-BötC and RTN/pFRG oscillators. They have shown that the dynamics of each oscillator can be represented by a stable limit cycle in some phase space. The phase space of a system of two coupled oscillators is a Cartesian product of the phase spaces of each oscillator. The behavior of this system can be represented by a trajectory on 2D invariant torus. If the ratio of oscillation frequencies of the two oscillators is rational (i.e., equal to N/M , for some integers N and M), then this trajectory is closed, indicating N/M synchronization between oscillators, where N and M represent numbers of rotations around two orthogonal circles that together span the torus (Rubin et al. 2011). These modeling studies provide mechanistic explanations for the emergence of RTN/pFRG oscillations and their interaction with the BötC/pre-BötC circuits representing the core of the respiratory CPG.

Intrinsic Neuronal Properties Involved in Rhythmic Bursting in the Brainstem and Spinal Cord

The mechanisms generating neural oscillations in the mammalian brainstem, particularly in the pre-Bötzinger Complex involved in control of respiration, and in the spinal cord (locomotor CPG), that persist after blockade of synaptic inhibition, remain poorly understood. Experimental studies in medullary slices from neonatal rodents containing the pre-BötC identified two mechanisms that could potentially contribute to

generation of rhythmic bursting: one based on the persistent or slowly inactivating I_{NaP} (Butera et al. 1999a, b; Koizumi and Smith 2008) and the other involving the calcium-activated nonspecific cation current (I_{CAN}) activated by intracellular Ca^{2+} accumulated from extracellular (e.g., calcium currents, I_{Ca}) and/or intracellular sources (Pace et al. 2007). The involvement and relative roles of these mechanisms in rhythmic bursting are still under debate. Several related models combining the above two mechanism have been developed (Rubin et al. 2009a; Toporikova and Butera 2011; Dunmyre et al. 2011; Jasinski et al. 2013). Jasinski et al. (2013) investigated Na^+ - and Ca^{2+} -dependent bursting generated in single cells and in a heterogeneous population of synaptically interconnected excitatory neurons with I_{NaP} and I_{Ca} randomly distributed within the population. They analyzed the possible roles of network connections, ionotropic and metabotropic synaptic mechanisms, intracellular Ca^{2+} release, and the Na^+/K^+ pump in rhythmic bursting activity generated under different conditions. They showed that heterogeneous populations of excitatory neurons with these properties can operate in different oscillatory regimes with bursting dependent on I_{NaP} and/or on I_{CAN} , or independent of both. The exact oscillatory regime and the operating bursting mechanism may depend on neuronal excitability, synaptic interactions, and relative expression of particular ionic currents. The existence of multiple oscillatory regimes and their state-dependency may provide explanations for different rhythmic activities observed in the brainstem and spinal cord under different experimental conditions.

Interestingly, the Na^+ - and Ca^{2+} -dependent bursting mechanisms can be unexpectedly connected. Brocard et al. (2013) have shown that the evoked locomotor-like activity in the isolated neonatal rodent spinal cord reduces the extracellular calcium concentration ($[Ca^{2+}]_o$) to 0.9 mM and increases the extracellular potassium concentration ($[K^+]_o$) to 6 mM. Such changes in $[Ca^{2+}]_o$ and $[K^+]_o$ trigger a rhythmic bursting activity in spinal interneurons that may represent elements of the respiratory CPG. The performed experimental studies and modeling have shown that the

emergence of this rhythmic activity critically involves a $[Ca^{2+}]_o$ -dependent activation of the persistent sodium current (I_{NaP}). These results suggest that the locomotor oscillations in the spinal cord may relay on the I_{NaP} -dependent pacemaker properties in spinal interneurons, which can be turned on and off by activity-dependent changes in $[Ca^{2+}]_o$ and $[K^+]_o$ (Brocard et al. 2013).

Vestibular System: Overview

Americo Migliaccio

Balance and Vision Laboratory, Neuroscience
Research Australia, University of New South
Wales, Sydney, NSW, Australia

Detailed Description

The vestibular system is our sixth sense. Not only does it contribute to our sense of orientation and movement in space but, via the vestibulo-ocular reflex (VOR), it stabilizes our vision, especially during rapid unpredictable head movements. Without the VOR our visual world would appear to move every time we undertook an activity that involves head movement, such as during walking, running, climbing, or driving on a bumpy road.

The vestibular organ is located in the inner ear next to the cochlear. As our head movements consist of rotations (nodding in affirmation) and translations (jumping up and down when happy), the vestibular organ comprises two sensor systems. The semicircular canals sense angular head rotations while the otolith organs sense linear head translations (see ► [“Vestibular Otoliths, Response to Vibration and Sound”](#)). Both the semicircular canals and otolith organs rely on specialized hair cells and the inertia of fluid (canals) or a gelatinous mass (otoliths) to bend the sensory hairs. Because there are two types of hair cells and because individual vestibular afferents receive input from different combinations of these hair cells, the signals coming from the vestibular periphery contain a wealth of sensory information that includes head-rotation velocity and acceleration, head linear acceleration, or tilt angle (see ► [“Peripheral Vestibular Signal Processing”](#)). This information is encoded in the signals coming from the peripheral vestibular organs but further processing occurs centrally (see ► [“Central Vestibular Signal Processing”](#)) to generate the appropriate three-dimensional (horizontal, vertical, and torsional) eye

movements required to stabilize vision and the muscle responses that equilibrate balance. Some of this processing is very rapid. For example, the direct pathway of the VOR consists of a three-neuron arc that has a transmission delay of ~7 ms in primates. In fact, the VOR is our fastest neural reflex.

The central vestibular neural circuitry, located in the vestibular nuclei of the brainstem, receives input from the vestibulo-cerebellum to sustain, modify, and train the vestibular response (see ► [“Vestibular Adaptation and Compensation”](#)). Thus, the vestibular system is an exquisitely adaptable system during normal function. For example, the VOR response increases almost immediately when needed to view close objects or scenes, as if that context had been pre-programmed and can be trained to increase or decrease when wearing magnifying or minifying lenses. The vestibular system also has the ability to recalibrate to compensate for permanent injury to one (complete injury) or both (incomplete injury) of the vestibular organs and their associated nerves. There are many causes of damage to the vestibular end organ and associated nerves. The most common of these include age-related cell loss, tumors, head trauma, ototoxic injury (e.g., by aminoglycoside drugs), Meniere’s disease, infection (meningitis and vestibular neuritis), and cochlear implantation (see ► [“Vestibular Function After Cochlear Implantation”](#)). About 1% of adults under 65 and 25% over 65 will have an injury to the vestibular organs. Other patients will have normal functioning vestibular organs and nerves but suffer from abnormalities of the vestibular organs that result in conditions such as benign paroxysmal positional vertigo or superior canal dehiscence syndrome. Because the vestibular system operates over a large range of head-rotation frequencies (0 to ~15 Hz) and comprises the canals and otolith organs, a range of diagnostic tests have been developed to test for the different conditions above including the following: head impulse testing (see ► [“Vestibular, Canal Testing: The Head Impulse Test”](#)), video (see ► [“Vestibular, Eye Movement Testing”](#)), imaging, and

vestibular evoked myogenic potential testing. For example, the head impulse test is used to determine the function of each of the six semicircular canals and their associated nerves during physiologically relevant rapid head rotations. For patients with complete vestibular organ loss, vestibular function can be restored by a vestibular prosthesis that senses head movements and transmits an appropriately encoded electrical signal to drive the vestibular nerves (see ► [“Vestibular Prosthesis, Interface”](#)). For prosthesis recipients and also patients with incomplete vestibular loss, vestibular rehabilitation is essential for maximum recovery (see ► [“Vestibular, Rehabilitation”](#)). Ideally, vestibular rehabilitation exercises are tailored for each patient so that compensatory mechanisms are best enabled. The accepted techniques developed to diagnose, cure, and rehabilitate vestibular injury have helped many patients because they are

based on our fundamental understanding of vestibular signals and their processing. This is the focus of the articles in this section.

Accumulation of Evidence in Decision-Making

Alexander C. Huk, Leor N. Katz and Jacob L. Yates
Departments of Neuroscience and Psychology,
Center for Perceptual Systems, The University of
Texas at Austin, Austin, TX, USA

Definition

Accumulation of evidence in decision making is the process by which noisy sensory information is sequentially sampled until sufficient evidence has accrued to favor one decision over another or others.

Detailed Description

The accumulation of evidence over time is a central topic in computational neuroscience spanning behavior, brain, and theory (Huk and Meister 2012; Shadlen et al. 2006; Usher and McClelland 2001): (1) it is a fundamental aspect of tractable forms of cognition, such as simple forms of decision making; (2) mathematical models of how

evidence could (and should) be accumulated are available and have a rich history of accounting for performance in laboratory tasks; and (3) there is an apparent disconnect between the hundreds of milliseconds over which animals can integrate evidence and the individual computing elements of the brain, neurons, which integrate their inputs over a small number of milliseconds.

Although accumulating evidence over time is a central component of both cognitive function and many statistical models for decision making, the current emphasis on this topic is likely driven by the simple fact that remarkably direct neural correlates of such temporal accumulation appear to have been found in the spiking responses of neurons in brain areas such as the posterior parietal cortex, prefrontal cortex, and other areas with premotor functions (Gold and Shadlen 2007).

Mathematical Foundations

The computational neuroscience of evidence accumulation starts with Bloch's Law, a fundamental principle of sensory processing (Bloch 1985). Bloch's Law is a description of temporal summation, such that if more time results in more signal, simple behaviors such as detection will show increases in accuracy that depend on the product of stimulus intensity and time. At longer durations, a breakdown in Bloch's Law is interpreted as the limit of the temporal summation properties of the transducer. Despite its historical significance, Bloch's Law is rarely applied to modern decision-making tasks, as it focuses on "sufficiently short" durations and does not explicitly model noise, a critical tool for manipulating difficulty in many decision-making paradigms.

As opposed to the linear dependence of accuracy on time of Bloch's Law, statistical models within the "sequential sampling" framework assume that significant noise is present and that by accumulating many samples, accuracy can be improved. Under the simplest conditions of independent additive noise at each instant in time, accuracy based on ideal temporal accumulation will improve as a function of the square root of time. This root-time improvement in accuracy is

directly related to the square root (n) term that many students will recognize from basic statistics.

This statistical point is the basis of a large family of models in the "sequential sampling" framework, a set of models built and adapted within statistics, physics, mathematical psychology, and neuroscience (Stone 1960; Watson 1979; Luce 1986; Link 1992; Ditterich 2006). In essence, these models assume that noisy information about a stimulus is sampled sequentially, until sufficient evidence has been accrued to favor a decision. For binary choices, the accumulation follows a noisy trajectory, where information is represented as a single quantity in which input supporting one hypothesis is evidence against another (i.e., H_1 vs. H_2). Mathematically, sampled evidence is weighted to support one of the two hypotheses and may be expressed as the ratio of likelihoods, the probability of observing the evidence ("e") given the hypothesis ($p(e|H_1)/p(e|H_2)$). The logarithm of this quantity may be summed over time to represent the degree of evidence accumulated in favor of one of the hypotheses over the other, termed the "log likelihood ratio." This value can be used to determine the optimal stopping rule for an accumulation process as implemented in the sequential probability ratio test (Wald 1947).

Evidence Accumulation in Models of Decision Making

This family of models has been extensively used to account for behavioral data and linked to psychological mechanisms: the number of samples required to reach a bound reflects decision time, and the identity of the bound reached reflects the decision. The weight of sampled evidence is a function of stimulus strength such that a strong stimulus in favor of H_1 will require fewer samples to reach the H_1 bound, resulting in faster reaction times and higher accuracy. For choices where H_1 and H_2 are equally likely, the bounds are equidistant from the starting point, the magnitude of which primarily reflects the tight coupling between decision time and accuracy: fast decisions come at the cost of accuracy, and high accuracy comes at the cost of time (the speed-accuracy

trade-off). A shift in starting point position towards H1 may reflect an *a priori* bias, resulting in a higher proportion of H1 choices over H2, with faster decision times.

The first major distinction between model types is whether they posit a single accumulator or multiple, racing accumulators. If there is a single accumulation process, models posit a pair of decision bounds (for a two-alternative paradigm), and the accumulation process starts in between these upper and lower limits. Thus, incoming evidence is “signed” with positive evidence pushing the accumulator towards the upper bound and negative evidence pushing the accumulator towards the lower bound. In typical “race” models, a pair of parallel and competing mechanisms each accumulates evidence in favor of their particular outcome, and the decision is determined by the first accumulator to reach its respective bound (Usher and McClelland 2001). If the signal and noise available to both accumulators are identical, such perfectly correlated racing accumulators make the same predictions as a single accumulator, despite the difference in hypothesized architecture. On the other hand, racing mechanisms can exhibit increasingly complex behaviors as additional parameters between them become statistically uncorrelated. Independent noise changes the behavior of racing versus single-variable accumulators, and more baroque models can behave quite differently than a standard single accumulator (Ditterich 2006).

The second major distinction within sequential sampling models is whether they model time as discrete or continuous. Discrete models are more straightforward to implement in computer code, while continuous models avail themselves to closed-form mathematics. While it is of course true that in the limit (i.e., as discrete time steps go to infinitesimals) discrete models become continuous, this requires some care in practice. It is critical that discrete approximations of continuous models be implemented using appropriately fine time scale steps. Otherwise, small rounding artifacts can manifest themselves in peculiar behaviors of the model. It is therefore advisable that discrete models be implemented with checks relative to known properties of the continuous-math

model. Modern computers make the prospect of fine time steps less of a practical (speed) concern, but counterintuitive or quirky predictions of a discrete modeling exercise should be interpreted with caution.

The Drift-Diffusion Model

Perhaps the most common model of evidence accumulation is the (continuous time) diffusion model, increasingly referred to as the “drift-diffusion to bound” model (DDM) (Shadlen et al. 2006; Ratcliff 1978; Ratcliff and Rouder 1998; Palmer et al. 2005; Ratcliff and McKoon 2008). It stands as a hub because it is mathematically tractable (i.e., the psychometric and chronometric functions can be derived analytically) and can be flexibly extended to capture a wide range of behavioral data. The simplest diffusion models are composed of three parameters: a drift rate, bound height, and accumulator noise. The drift rate relates the stimulus units to a rate of drift of the diffusion process. The bound height is the stopping point (for two alternatives, e.g., H1 and H2, symmetrically above and below an unbiased start point). Accumulator noise is invariant across stimulus conditions and describes the noise in the accumulation process. This version of the model is overdetermined and can be rewritten as a two-parameter model with bound height or noise fixed. The diffusion model can be easily extended. For example, an additive nondecision time may be included to account for nondecisional sensory transduction and motor execution delays. Parameters added to model trial-to-trial variability in drift rate and residual time can capture phenomena like delayed reaction times for incorrect trials (Ratcliff 1978; Ratcliff and Rouder 1998; Ratcliff and McKoon 2008).

Evidence Accumulation in Neurons

The presence or implementation of diffusion-like algorithms in the brain is still a matter of significant interest and contention. The first direct evidence for a putative diffusion process in the brain

was observed in the spike rates of single neurons in the lateral intraparietal sulcus (LIP) of macaque monkeys during a stochastic motion discrimination task where the experimenter can control the amount of motion (the “evidence”) on a single trial (Shadlen and Newsome 2001; Roitman and Shadlen 2002). Neurons in the LIP have a mean spike rate that ramps up for choices that result in an eye movement into their response field (RF) and ramps down for choices out of their RF. Moreover, the slope of the ramp is steeper for trials with more evidence, mirroring the drift rate of a diffusion process. Time-varying motion stimuli have further supported the notion that LIP neurons reflect temporal accumulation (integration) of relevant sensory signals (Huk and Shadlen 2005; Kiani et al. 2008). Other work has shown that the spike rates of single neurons in a range of cortical and subcortical brain areas also exhibit correlates of a diffusion process (Ratcliff et al. 2007; Ding and Gold 2012a, b).

To date, these early investigations shed little light on exactly how neurons might implement time integration, yet understanding the biophysical mechanisms may provide significant insights into the cognitive constraints of evidence accumulation (Huk and Meister 2012; Wong and Wang 2006). Likewise, the current focus on responses as averaged over neurons, trials, and sessions paints a categorical and potentially inaccurate picture of what occurs on the time scale of individual trials and decisions (Churchland et al. 2011). The next generation of work on this topic will hopefully unpack how the theoretical mechanisms of evidence accumulation are implemented by real neural circuits (Bollimunta et al. 2012).

[Auditory recognition](#); [Sound source identification](#)

Definition

Timbre is what allows a listener to distinguish two sounds that have otherwise the same subjective pitch, loudness, location, and duration. For instance, when orchestral musicians tune at the beginning of a concert, they all play the same note, but one can still tell the difference between instruments. This is largely because of timbre.

Detailed Description

The standard definition of timbre has several shortcomings. First, it says what timbre is not, rather than what it is. Second, it relates to the comparison between two sound tokens, whereas

a more useful function for hearing is to associate a single timbre directly with a sound source (the timbre of the piano, the timbre of the voice of a friend). Perhaps as a consequence, there is still a lively debate about the acoustic features, mental representations, and neural mechanisms underlying timbre recognition. Here, we first outline the basic principles that make timbre such a powerful potential cue for sound source identification. Then we put forward two possible approaches to timbre, which we follow into the fields of acoustics, perception, neural mechanisms, and computational applications.

Why Do Different Sound Sources Produce Different Timbres?

Sound sources are physical objects that come in all shapes and sizes. Sound is produced when some energy makes the object vibrate. The vibrations spread around the source, which then propagate to the air and reach the ear of a listener in the form of pressure waves (Fig. 1). Simple physics shows that the wave pattern at the ear can contain a lot of information about what happened at the source (Helmholtz 1877). For instance, if the energy input was brief, such as a door knock, the chances are that the sound itself will be brief and have most of its energy concentrated around the time of the knock. After the knock, the way the door continues to vibrate is closely related to its geometry, because some wave patterns are consistent with some geometries and some are not. One such rule is that waves with low frequency and thus a long wavelength are not stable within small objects. Thus, the proportions of different frequency components that combine to make the sound of a door knock will be constrained by the size of the door. Other, more complex rules apply, depending on the shape of the object, the nature of the materials involved, and so on.

Being able to decode the intricate links between wave patterns and sound sources is extremely useful for humans and other animals. It allows the auditory system to serve as a warning sense, for instance, to identify sound-producing objects that are out of sight. For people, it is also

Acoustic Timbre Recognition, Fig. 1 Visual representations of four sounds with the same duration, loudness, and pitch, only differing by timbre. Each panel displays a time-frequency analysis derived from an auditory model (see Agus et al. 2012 for details). Briefly, color indicates the pattern of energy within frequency channels (y-axis) as it evolves over time (x-axis). The top trace is the corresponding pressure waveform. The right-hand trace is

the average energy over time. The two instruments illustrate classic dimensions of timbre: depending on the sound source and how it is excited, the attack time can be fast (piano) or slow (trombone); the spectral center of mass can be high (piano) or low (trombone). The two vowels illustrate that other possibly more complex features may also be used to distinguish, e.g., vowels from instruments or vowels from each other

the very basis of spoken language: vowels and consonants are produced by modulating the shape of the vocal apparatus, resulting in changes in timbre that are the building blocks of oral communication.

Dimensions Versus Features

There is no consensus on what makes timbre recognition possible for human listeners. To outline current controversies, it is useful to consider two opposite viewpoints (Fig. 2). A first view is that timbre is composed of a reasonably small number of perceptual dimensions, which are subjective descriptions of sound just as pitch or loudness. Such dimensions must be metameric, in that several different sounds may project to the same point on the dimension.

Acoustic Timbre Recognition, Fig. 2 Schematic representation of the dimensions approach versus the features approach for timbre. (a) For the dimensions approach, all different timbres can be projected in a low-dimensional space of continuous dimensions. (b) For the features approach, each timbre is defined by a set of distinctive features among a very large and unordered set of possible features

A second view is that timbre recognition relies on the distinctive features of a given sound source, learned through experience and selected among a very large space of potential features. The grain of a friend's voice may be unique, which is what allows us to recognize her instantly. Such features would be conceptually different from dimensions in that a feature does not necessarily apply to all possible sound sources; in fact, it is precisely because it is unique to only a few sources (or even a single source) that it could be efficient for recognition.

It is likely that a full account of timbre will lie somewhat in between these two simplified hypotheses. However, for clarity, we continue to contrast each approach for different aspects of timbre research.

Sound Representations

To investigate timbre, it is useful to represent sound visually. Classically, this has been done with tools such as the trace of the pressure waveform over time; the spectral analysis of component frequencies through, e.g., Fourier analysis; or spectro-temporal transformations such as the short-term Fourier transform or wavelet analyses. More recently, computational models that aim to mimic peripheral or central auditory processing have been suggested (e.g., Patil et al. 2012).

In the “dimensions” approach, summary statistics are computed on sound representations to define what are referred to as descriptors of timbre. For instance, the center of mass of all frequency components of a sound produces a single number that is correlated with the apparent “brightness” of a sound (McAdams et al. 1995). In the “features” approach, the tendency is rather to maximize the richness of the representation, by including complex spectro-temporal selectivities. Such a feature-based representation need not be orderly. It can be over-complete with thousands of partially overlapping features, or sparse, in the sense that a given sound would only activate a small number of features within that large possible space (Hromádka and Zador 2009).

Perceptual Data

The basic aim of the dimensions approach is to uncover the nature and number of the perceptual dimensions underlying timbre. To this effect, statistical techniques based on multidimensional scaling have been used: a pair of sounds is presented to the listener, who has to rate how similar to each other the two sounds seem. This is repeated for all possible pairs within a given sound set. Then, the similarity judgments are treated as perceptual distances and used to obtain the dimensionality and geometry of the corresponding mental representation. For musical instruments, classic studies point toward two to three main dimensions: one related to the attack time, one related to the spectral center of mass, and one additional dimension that is less consistently observed (Grey 1977; McAdams et al. 1995). More recent investigations, using both multidimensional scaling and verbal descriptions, suggest five main dimensions with more complex interpretations (Elliott et al. 2013).

In the features approach, the focus is not on similarity but rather on the recognition of the sound source. Again, using musical instruments, fast recognition times have been observed (Agus et al. 2012), and recognition was found to be preserved even for severely impoverished signals (Suied et al. 2013). Moreover, recognition was faster and more robust for highly familiar sources such as the human voice, an observation that could not be traced back to simple acoustic dimensions (Agus et al. 2012). These results strongly suggest the existence of diagnostic features that were learned by listeners, through experience, to recognize, e.g., voices in a robust and efficient manner.

Neural Bases

Neural correlates of generic timbre dimensions have been investigated with brain imaging. Using an EEG paradigm to probe sensory memory known as mismatch negativity, it has been found that timbre dimensions such as brightness

or onset time could each be represented separately within auditory cortex (Caclin et al. 2006).

From the features perspective, single-unit recordings have uncovered a rich variety of selectivities, at many levels of the auditory system, often without any obvious ordering principle (other than by frequency). Using linear analysis techniques such as reverse correlation, spectro-temporal receptive fields have been derived. Various spectral and temporal modulation preferences have been observed, e.g., in the primary auditory cortex (Depireux et al. 2001). Adding a nonlinear component to the analysis adds another layer of complexity (Machens et al. 2004). Furthermore, the neural encoding of timbre may interact with supposedly independent sound characteristics, such as pitch or location (Bizley et al. 2009).

A further question is whether the identity of a source will be encoded by the activity of a wide network shared by many sound sources or by the activity of only a small network specifically tuned to that source category. Evidence has been put forward for both models. Using fMRI, the identity of a sound source can be inferred from distributed activity (Staeren et al. 2009). At the same time, there are clear indications of localized brain areas specialized for familiar sound sources such as the human voice (Belin 2006).

Timbre Recognition by Machines

There are several applications for acoustic timbre recognition, such as speaker identification or music information retrieval. Even though the techniques used are fast evolving and a detailed description is beyond the scope of this section, it is interesting to note that the dimensions versus features contrast can also be seen in the architectures of the computational systems.

Automatic speech recognition, which can to some extent be viewed as a timbre-decoding exercise, has a long tradition of performing classification on a small number of generic coefficients (e.g., mel-frequency cepstrum coefficients

and their variants (Hermansky 1990)). For musical instruments, a descriptor-based approach has been directly inspired by the perceptual dimensions of multidimensional studies, with a reasonably small number of explicit descriptors (Peeters et al. 2011). However, other systems exist that are based on feature generation from a huge potential feature space, followed by ad hoc selection for a given classification task (Coath and Denham 2005; Pachet and Roy 2009). For musical instrument classification, machine-learning algorithms applied on a high-dimensional auditory model representation have also been successfully demonstrated (Patil et al. 2012).

Perspectives

The outstanding issues for timbre research will probably benefit from considering the various strategies available to a listener. For instance, when asked for subjective distance judgments, the most reasonable thing to do may be to abstract common dimensions to a sound set, and then use those for the comparisons. However, when asked to recognize a source as fast as possible, the mere presence of a diagnostic feature may be sufficient. The set of useful timbre dimensions or features can also depend on the task: for a same set of spoken words, different strategies are used if listeners are asked to identify the speaker or report the word content (Formisano et al. 2008). Finally, the very neural representation of timbre may be dynamically tuned to the immediate acoustic context, through rapid plasticity (Fritz et al. 2003). A fundamental reason that makes timbre so elusive may therefore be that timbre recognition is a profoundly adaptive mechanism, able to create and use opportunistic strategies that depend on the sounds and task at hand.

Back-propagating spikes

Definition

Action potential (AP) back-propagation, as opposed to forward-propagation along the axon, consists of the conduction of the axonally initiated AP along neuronal dendrites, in the form of a depolarization sustained by both active and passive mechanisms. The amplitude of the depolarization generally decreases along the dendrites with increasing distance from the soma; the degree of attenuation is highly variable and depends on the neuronal type.

Detailed Description

Simultaneous recordings from dendrites, soma, and axon have shown that action potentials are generally initiated in the axon initial segment, the region with the lowest threshold for AP initiation (Stuart et al. 1997; Spruston et al. 2016). In addition to canonical forward-propagation along the axon to the presynaptic terminals, APs rapidly invade the soma and propagate back into the dendrites, where voltage-dependent channels actively support the depolarization (Spruston et al. 2016). As opposed to all-or-none axonal APs, the amplitude of back-propagating action potentials (bAPs) can be modulated and generally decreases along the dendrites with the distance from the soma. The extent of back-propagation varies widely in the different neuronal types investigated, ranging from non-decremental to almost passive (Fig. 1).

Determinants of Action Potential Back-Propagation

The main factors that determine the extent of action potential back-propagation are (a) density and properties of dendritic voltage-dependent channels, (b) neuronal morphology, and (c) neuronal activity (firing history and concurrent inputs).

Dendritic voltage-dependent channels: Different neuronal types have distinct distributions of dendritic voltage-dependent ion channels (Migliore and Shepherd 2002, 2005; Magee 2016). AP back-propagation is sustained by dendritic voltage-dependent Na^+ channels and activates Ca^{2+} channels (Johnston et al. 1996). Dendritic K^+ channels can modulate the

amplitude and extent of back-propagation; their role has been most extensively studied in hippocampal CA1 pyramidal neurons, where the density of A-type ($\text{Kv}4.2$) K^+ currents increases along the apical dendrites with the distance from the soma (Johnston et al. 2000). Therefore, the extent of back-propagation along the dendrites depends on the relative density of dendritic Na^+ and K^+ channels (see the interactive example in Fig. 2) and is affected by channel modulation by neurotransmitters or plasticity (Johnston et al. 1999; Magee and Johnston 2005).

Morphology: It is difficult, if not impossible, to experimentally assess the exclusive contribution of dendritic morphology, and the relation to ion channel properties, to action potential back-propagation. However, computational simulations have shown that significant differences in propagation can be attributed exclusively to dendritic geometry. When the same active and passive parameters were inserted in compartmental models with reconstructed morphologies of various neuronal types, there was a strong correlation between back-propagation and dendritic geometry (branch points and relative impedance; see Fig. 3; Vetter et al. 2001; Spruston et al. 2016). These results indicate that dendritic morphology and branching patterns have a fundamental role in shaping back-propagation.

Neuronal Activity: Dendritic excitability and AP back-propagation are highly dependent on the membrane potential and therefore on concurrent neuronal activity, as well as the firing history of neurons. Hippocampal CA1, entorhinal layer V, and neocortical layer V (but not layer II/III) pyramidal neurons show a significant

Action Potential Back-Propagation,

activity-dependent decrease in the amplitude of bAPs along the apical dendrites during high-frequency trains (Johnston et al. 1999; Gasparini 2011). In CA1 and entorhinal layer V pyramidal neurons, this behavior is mostly due to a slow, cumulative inactivation of dendritic Na^+ channels and can be reduced by neurotransmitters activating protein kinase C (Johnston et al. 1999; Magee 2016). In addition, the amplitude of bAPs at distal locations can be boosted by appropriately timed synaptic inputs (see the interactive example in Fig. 4), which promote back-propagation by inactivating A-type K^+ channels or by facilitating Na^+ channel activation (Migliore et al. 1999;

Spruston 2008). On the other hand, the bAP-induced depolarization and Ca^{2+} influx can be significantly reduced by inhibition, achieved experimentally through either GABA uncaging or stimulation of individual of inhibitory interneurons (Boivin and Nedivi 2018).

Functional Role

The depolarization and Ca^{2+} influx associated with bAPs provide feedback to the region that received the synaptic input, signaling that the neuron has generated an output. This feedback signal has important consequences on neuronal firing and synaptic plasticity. In neocortical layer V neurons, pairing bAPs with a distal synaptic input initiates a dendritic Ca^{2+} spike (back-propagation-activated Ca^{2+} or BAC spike), which results in a burst of somatic APs, possibly a marker for cortical associations (Spruston 2008; Palmer et al. 2016). In many neurons, the appropriate timing of bAPs and EPSP can cause long-term changes in synaptic efficacy (spike-timing-dependent plasticity or STDP). The depolarization associated with the bAP provides the coincidence detection needed for the removal of Mg^{2+} from NMDA glutamatergic receptors, triggering plasticity phenomena (Maheux et al. 2016). The Ca^{2+} influx caused by bAP has also been suggested to mediate dendritic release of neurotransmitters (Ludwig and Pittman 2003). The functional role of bAPs in relation to animal behaviors is more difficult to establish, since dual dendritic and somatic recordings in vivo are extremely more challenging than in vitro (but see Roome and Kuhn 2018 for recent developments); therefore dendritic signals cannot be unequivocally interpreted (Palmer et al. 2016).

Techniques to Study Back-Propagation

The interaction of experimental and computational methods has been essential to understanding the mechanisms underlying AP back-propagation, allowing intrinsic limitations of the individual approaches to be overcome.

Direct **electrophysiological recordings** with the patch-clamp technique in different configurations have been performed at various distances from the soma mostly on larger diameter dendrites

Action Potential Back-Propagation,

(Gurkiewicz and Korngreen 2006), providing information on channel distributions (Magee 2016) and back-propagation (Waters et al. 2005). **Fluorescence imaging techniques** (using Ca^{2+} - or voltage-sensitive dyes) have been used to assess smaller dendrites and compartments and/or to obtain data from many dendritic locations in a single neuron. More recently, **genetically encoded calcium and voltage indicators** have been developed and expressed in neurons,

pushing the boundaries of large-scale, high-resolution monitoring of neuronal activity (Deo and Lavis 2018). These experimental techniques have advantages and limitations (Waters et al. 2005; Scanziani and Häusser 2009). For this reason, the investigation of AP back-propagation and its functional roles have greatly benefitted from **computational models** that use biophysically and morphologically accurate implementations. These models have supported, explained, and predicted

Action Potential Back-Propagation, Fig. 4 Effect of pairing a synaptic input with AP back-propagation in CA1 pyramidal neurons. If the timing is appropriate, bAP is boosted by the synaptic input (red trace). An interactive example, where the timing between AP and synaptic input can be modified, is available at <http://senselab.med.yale.edu/ModelDB/ShowModel.asp?model=148646>

several experimental findings on AP back-propagation (Schaefer et al. 2003; Watanabe et al. 2002). An optimal approach to studying and understanding AP back-propagation is therefore a synergistic loop, with experiments suggested by computational simulations, and experimental outcomes used to constrain the models.

Action Potential Initiation

Dejan Zecevic and Marko Popovic
Department of Physiology, Yale University
School of Medicine, New Haven, CT, USA

Synonyms

[Spike initiation](#)

Definition

Electrical impulses (action potentials (APs) or spikes) which encode and transmit information in the nervous system are initiated in the proximal anatomical region of the axon termed axon initial segment (AIS). The voltage threshold for spike initiation and the exact location and length of the spike trigger zone (TZ) within AIS, as well as the amplitude and waveform of the action potential in different neuronal classes, depend on the geometry and passive electrical properties of a neuron as well as on the type, spatial distribution, and density of a variety of voltage-sensitive ionic channels.

Detailed Description

There is little disagreement over attributing action potential initiation to a site in the axon initial segment (AIS) under most circumstances. The question of the exact location and length, however, of the spike trigger zone (TZ) in the axon, as defined in functional terms, is less clear. In most studies, the spike TZ was characterized by a single parameter, the distance from the soma, implying a point of initiation. The length of the initiation site, however, is fundamentally important because successful initiation and propagation of the action potential wave requires that a certain length of an axon is brought to the threshold for excitation (Rushton 1937). Besides the fundamental importance of characterizing the action potential (AP) initiation site, the spike TZ location and

length have a recently discovered specific role in tuning neuronal computation underlying a well-defined function in auditory neurons which mediate sound source localization (Carr and Boudreau 1993; Kuba et al. 2006; Kuba and Ohmori 2009). Moreover, subsequent studies of Kuba et al. (2010) and Grubb and Burrone (2010) reported a novel finding that the structure of the spike TZ mediates an intrinsic plasticity of the axon and regulates the final stage of integration of synaptic inputs. This places a great significance on our ability to directly probe the location and length of the spike TZ under different conditions. The available information regarding TZ plasticity is based on structural data (Grubb and Burrone 2010; Kuba et al. 2010). Molecular structure of the spike TZ, however, is indirectly correlated with function in a way that is not fully understood (Fleiderovich et al. 2010; Johnston 2010). Thus, the anatomical data require functional confirmation. The location and length of the spike TZ have been difficult to measure directly using electrodes because extracellular recordings cannot be interpreted with sufficient accuracy and intracellular recordings lack the necessary spatial resolution (e.g., Meeks and Mennerick 2007). Membrane potential imaging (Vm imaging) offers a unique advantage of high spatial resolution compared with electrical recordings and has been used to directly measure the location of action potential initiation in invertebrate neurons (Zecevic 1996; Antic et al. 2000) and mammalian axonal arbors (Palmer and Stuart 2006; Palmer et al. 2010). This technique was recently improved and utilized to characterize functionally relevant parameters of the spike TZ in layer 5 pyramidal neurons of the cerebral cortex (Popovic et al. 2011). The measuring technique and the analysis of data used to determine the location and length of the spike trigger zone are shown in Fig. 1.

A typical experimental measurement used to determine the location and length of the spike TZ is illustrated in Fig. 2. These two parameters are obtained directly from multisite optical recording of the membrane potential transients (Fig. 2a–c) either by investigating spike latencies at the soma/axon hillock and more distal axonal recording locations or by the inspection of the spatial

distribution of membrane potential as a function of time. The soma–axon latency is plotted against recording distance from the edge of the soma in Fig. 2d. An alternative way to derive the same information from the data is to analyze a time sequence of color-coded frames showing the spatial maps of AP amplitude (Fig. 2e). The result of this analysis is a temporal series of individual frames separated by 10 μ s; each showing the spatial map of membrane potential at one point in time. In Fig. 2e, four frames from this series were selected to illustrate characteristic regions along the axon that can be clearly identified during AP initiation. The red region closest to the soma was the first to cross the threshold value and reach 50% amplitude (time point 0 μ s) and was identified as the AP TZ. The more distal red region appearing with a delay (45 μ s time point) is likely to be the first node of Ranvier, corresponding to the issuance of an axon collateral, as indicated in the high-resolution image (Fig. 2a). The same data are shown in Fig. 2f as AP signals scaled to the same height and compared on an expanded time scale. The two red traces show AP signals from the two red areas in Fig. 2e corresponding to the spike TZ and the first node. The green dashed trace is the AP signal from the axon hillock. The green trace is the AP signal from the first internodal region. The mean length of the TZ determined from the type of data shown in Fig. 2 was $16.5 \pm 1.1 \mu$ m with the mean center located at $28.9 \pm 1.0 \mu$ m from the edge of the soma.

Vm imaging can be used to analyze the spatial pattern of AP propagation as revealed by monitoring transmembrane potential over longer sections of individual myelinated axons. Previously, this information was not available for any neuron. A representative experiment (well-stained neuron characterized by long axons in one plane of focus close to the surface of the slice) is illustrated in Fig. 3. The spatial plot of the soma–axon latency along an axonal section of approximately 300 μ m clearly identified the position of the spike TZ and putative nodes of Ranvier; all characterized by localized reduction in soma–axon latency typical for saltatory conduction (Fig. 3a). The spatial plot of AP latency provides a functional readout for the position of the nodes of Ranvier. Figure 3c shows

The first minimum identifies the location and length of the spike TZ. **(e)** Time sequence of frames showing spatial profile of colour coded relative V_m amplitude in the axon at four characteristic time points: 0 μs – AP initiation at TZ; 45 μs and 80 μs – invasion of the first node; 240 μs – peak depolarization. **(f)** Comparison of AP signals from four characteristic locations on an expanded time scale. The measured data points and cubic spline interpolation curves are shown. Red traces – TZ and first node; green dashed trace – axon hillock; green trace – first internodal region. Membrane potential colour scale shown on left

a color-coded spatial map of the depolarizing AP wave at one characteristic point in time which indicates the position of the spike TZ as well as nodes of Ranvier.

The voltage-sensitive dye imaging approach allows determination of the location and length of

the spike TZ in the AIS of pyramidal neurons, as defined in functional terms. In addition, it is possible to characterize the AP propagation pattern in the main axon and collaterals. It is plausible to predict that this approach will facilitate the analysis of signal interactions underlying input-output

Action Potential

Initiation, Fig. 3

transformations carried out in neuronal processes of different classes of nerve cells. The question of TZ dimensions is of fundamental importance because the size of the initiation site is a critical functional parameter. Successful initiation and propagation of the action potential wave requires that a certain length of an axon is brought to threshold for excitation to generate an action current large enough to propagate. This follows from intuitive considerations, from the classical theory (Rushton 1937), as well as from more recent experimental studies (Colbert and Pan 2002; Meeks and Mennerick 2007). Additionally, Na⁺ channel clustering in the axon, which is critical in determining the spike TZ location and length, serves an important specific function in tuning neuronal computation underlying a well-defined function (sound localization) in auditory neurons (Carr and Boudreau 1993; Kuba et al. 2006; Kuba and Ohmori 2009). These findings advocate that the size and position of the spike TZ might be cell specific in other central neurons, depending on their function. Additionally, new data (Kuba et al. 2010; Grubb and Burrone 2010) show that the structure (and, by extrapolation, the function) of the spike TZ participates in neuronal plasticity and might, in fact, be one of the key factors controlling neuronal excitability and computation (Grubb and Burrone 2010; Kuba et al. 2010; Rasband 2010).

Definition

Models of adaptation in sensory cortices provide a functional and/or mechanistic description of the changes in neural responses and perception caused by sensory stimuli observed in the recent past. Sensory systems compute dynamic representations of the environment: cortical neurons typically adapt their “code” according to the recently received sensory input. This continuous recalibration is reflected in changes in neuronal response properties and has been interpreted as an adjustment of the limited dynamical range to compensate changes in the environment or changes in the observer. Functional models of sensory adaptation have linked these findings to optimal coding. Moreover, adaptation has also been studied in biophysical and network models, with the goal of understanding the mechanisms that give rise to adaptation in biological cortical circuits.

Detailed Description

Sensory adaptation refers to the changes in neuronal responses and perception caused by a prolonged exposure to sensory stimuli. Adaptation

is a rapid form of plasticity that has a reversible effect on neuronal selectivity: responses adapt (on short time scales) and recover to their pre-adapted state when the source of adaptation is removed. It is found ubiquitously across different sensory modalities (visual system (Kohn 2007; Clifford et al. 2007); auditory system (King et al. 2011); whisker system (Petersen et al. 2009)).

In psychophysical experiments, it can be shown that adaptation alters perception: prolonged exposure to a stimulus typically leads to “repulsive” aftereffects, which means stimuli similar to the adapting stimulus appear to be more different from the adapting stimulus than they actually are. An example is the tilt aftereffect, in which – after prolonged viewing of oblique lines – vertical lines appear briefly as if they were tilted in the opposite direction (see ► “Visual Aftereffects, Models of”).

Here, we focus on (1) functional models of the computational principles that may underlie the adaptive encoding of sensory information and (2) models of the neuronal and synaptic mechanisms giving rise to adaptation in cortical circuits.

Adaptation as Optimal Coding

Sensory systems must encode natural stimuli which change over many orders of magnitude with the limited dynamical range of neuronal firing rates. Adaptation has been proposed to serve for adjusting the sensory representation to the current statistics of the ever changing environment (Fig. 1). This was formalized in the *efficient coding hypothesis* (grounded in information theory), which states that sensory systems seek to provide an efficient representation of the natural environment by maximizing their information transmission capacity (Barlow 1961; Laughlin 1981; Wark et al. 2007). Given the statistics of the environment, this hypothesis predicts the optimal input–output behavior of a single neuron (Fig. 1) and how it should adapt to the mean and variance of the current stimulus intensity distribution.

Experimental evidence for efficient coding has been found across a wide range of sensory modalities and species: contrast adaptation in the visual system (Kohn 2007; Clifford et al. 2007), fly visual system (Laughlin 1981; Fairhall et al. 2001), mid-brain of guinea pigs (Dean et al. 2005), inferior colliculus of cats (Kvale and Schreiner 2004),

Adaptation in Sensory Cortices, Models of,

Fig. 1 Adaptation to the mean and the variance of incoming sensory stimuli. According to the efficient coding hypothesis, a change in the stimulus distribution (top) should yield an adaptive change of a neuron’s transfer function (bottom)

songbird auditory forebrain (Nagel and Doupe 2006), and rat barrel cortex (Maravall et al. 2007).

In a similar spirit, adaptation has also been linked to Bayesian inference, tackling questions such as how to optimally combine sensory observations with prior knowledge about the stimulus distribution (Doya et al. 2007). Adaptation could be interpreted as changing the prior distribution within the Bayesian theory of perception, or even the likelihood model could be affected by adapting stimuli (Stocker and Simoncelli 2006). How cortical circuits might implement Bayesian inference is an active research topic.

Modeling Underlying Neural Mechanisms

A different class of models aims at understanding the neuronal mechanisms that underlie adaptation. In some cases the mechanisms have been studied in detail experimentally, an example is contrast adaptation in the visual system. Adaptation shifts the contrast response curve of individual neurons toward higher contrast levels, and this can be well explained by the hyperpolarization of individual neurons caused by the activation of intrinsic channels (Sanchez-Vives et al. 2000). This mechanism accounts for a decrease in a neuron's firing rate due to sustained stimulation and is usually called spike-frequency adaptation; for a phenomenological model, see Benda and Herz (2003).

Often, however, the mechanisms underlying adaptation are not well characterized experimentally. Models can serve to integrate existing data and to create testable predictions in order to discern different potential mechanisms. An example is orientation adaptation, in which the prolonged exposure to a visual stimulus of a particular orientation yields changes of individual neuronal tuning curves in the early visual system (Dragoi et al. 2000) (see Fig. 2). A potential mechanism underlying this adaptation phenomenon, in addition to spike-frequency adaptation, is short-term synaptic depression. This form of rapid and reversible plasticity leads to a decrease of synaptic efficacy lasting from milliseconds to several seconds, due to prolonged presynaptic activity. This

timescale is comparable to the timescale of orientation adaptation, but synaptic depression has mostly been studied in vitro, and direct experimental evidence demonstrating that it is involved in orientation adaptation is lacking. Synaptic depression can be described by a change in transmitter release probability in a phenomenological model (Abbott et al. 1997; Tsodyks and Markram 1997). Computational studies have investigated how synaptic depression, spike-frequency adaptation, and other mechanisms contribute to adaptive changes of visual cortical neurons. The different studies do however reach different conclusions about which particular intrinsic or circuit mechanism is the most likely origin of orientation adaptation (Bednar and Miikkulainen 2000; Chelaru and Dragoi 2008; Cortes et al. 2011). We argue that for a full understanding of adaptation mechanisms in early visual areas, it is necessary to study how adaptation interplays with the dynamics of local circuits, which are dominated by strong, approximately balanced, excitation and inhibition (Stimberg et al. 2009).

On the other hand, computational network models have elucidated the link between orientation adaptation and the psychophysically observed tilt aftereffect, which has long been a challenge (Teich and Qian 2003). Computational models showed how adaptive changes in the location, the width, and the magnitude of single neuron tuning curves give rise to characteristic changes in population responses (Clifford et al. 2000; Compte and Wang 2006). In fact, the relationship between changes in experimentally measured single neuron tuning curves and the response of a population of neurons to a single stimulus (which is thought to underlie perception) can be counterintuitive (Fig. 2). For example, when neuronal tuning curves shift *away* from the adapting orientation (as typically observed experimentally), the corresponding population activity shifts *toward* the adapting orientation (Fig. 2a). If, on the other hand, adaptation only causes a suppression of neuronal responses close to the adapting stimulus (Fig. 2b), the result is a shift of the population activity *away* from the adapting stimulus (as observed in the tilt aftereffect). Considered together, the combination of adaptive changes

Adaptation in Sensory Cortices, Models of, Fig. 2 Example of the relationship between adaptive changes in single neuron tuning curves and changes in the population activity, which is thought to underlie perception. **(a)** Adaptation shifts response curves of individual neurons away from the adapting stimulus. Shown are the tuning curves (responses of a neuron to visual stimuli of different orientation) of three neurons with preferred orientation 0°, 20°, and 40° (*thin lines* before adaptation, *thick lines* after adaptation; *triangle* indicates the adapting

stimulus). **Right:** The *repulsive* tuning curve shifts correspond to a shift of the population activity (response of a population of neurons to a particular stimulus) *toward* the adapting stimulus. The neuron label is determined by each neuron's preferred orientation. **(b)** Same as **(a)**, but now adaptation suppresses responses of individual neurons with preferred direction close to the adapting stimulus. **Right:** This corresponds to a shift of the population activity *away* from the adapting stimulus

observed at single neuron level in visual cortex is indeed consistent with the observed changes in perception (Jin et al. 2005). Note that in this framework it is commonly assumed that adaptation alters encoding in sensory cortical neurons, whereas downstream areas “reading out” the stimulus-related information are unaware of adaptation (Seriès et al. 2009). The predicted perceptual effect also depends on the hypothetical link between population activity and perception, that is, on the “read-out” strategy (such as peak activity, population vector, or maximum likelihood decoding).

More recently, there has been increasing interest in studying high-level adaptation effects, including face adaptation (Webster 2011) and adaptation to the perception of causal interactions

(Rolfs et al. 2013). Computational modeling will be helpful in answering interesting questions related to these phenomena, such as to what degree high-level effects can be explained by adaptation to low-level features or how they arise across the processing hierarchy due to recurrent interactions between cortical areas.

Definition

Adaptive stimulus optimization refers to an experimental approach in neuroscience where neuronal or behavioral responses to stimuli presented on previous trials are utilized to adaptively generate new stimuli in an iterative, closed-loop manner, usually by optimizing an objective function. There are different choices for the objective function. For example, if the objective function is the neural response itself, the optimization procedure finds an optimal stimulus that drives maximum

response or is at least a local optimum in the stimulus space. When the objective function is the mutual information between the responses and the unknown parameters of a stimulus-response model, the optimization finds the stimulus set that yields the most accurate parameter estimation.

Detailed Description

Overview

Traditional experiments in the neurosciences have typically a fixed set of stimuli chosen *a priori* to elicit responses from neurons in an open-loop paradigm, with data analysis and model fitting taking place post hoc. In recent years, with increases in computer power and improvements of algorithms, there has been a growing interest in adaptively generating stimuli online during the course of experimentation in an iterative, closed-loop manner, where neuronal responses from previous trials are used to generate new stimuli (Benda et al. 2007; DiMattina and Zhang 2013; Potter et al. 2013; Park and Pillow 2016). This general paradigm is illustrated schematically in Fig. 1.

Adaptive stimulus optimization has long been used in psychophysics for estimating sensory thresholds (Watson and Pelli 1983; Kontsevich and Tyler 1999) and enjoys a large body of theoretical results from the statistics and machine learning literature (Paninski 2005; Chaloner and Verdinelli 1995). In sensory neuroscience studies, stimuli have been adaptively optimized for a wide variety of experimental goals, including maximizing neural firing rates (O'Connor et al. 2005; Chambers et al. 2014), finding maximally informative stimulus ensembles, (Machens et al. 2005), and estimating and comparing models of sensory processing (Lewi et al. 2009; DiMattina and Zhang 2011; Tam 2012; Park and Pillow 2012, 2016). In addition to applications in systems-level sensory neuroscience, closed-loop approaches have also been applied in many diverse areas including cognitive science, cellular neurophysiology, and brain-computer interfaces (Myung et al. 2013; Potter et al. 2013).

Adaptive Stimulus Optimization,

Fig. 1 Schematic illustration of adaptive stimulus optimization, where responses to preceding stimuli are used to generate subsequent stimuli in a closed-loop manner (Reproduced from DiMattina and Zhang 2013)

Optimizing Firing Rate

Methods for adaptive optimization of neuronal firing rate fall broadly into two categories: (1) hill-climbing methods and (2) genetic algorithms. Hill-climbing methods utilize local perturbations of a reference stimulus to estimate the local response surface from noisy neural responses, iteratively moving the reference stimulus in a direction (e.g., the gradient) which increases neural firing rate (Harth and Tzanakou 1974; O'Connor et al. 2005; Nelken et al. 1994; Koelling and Nykamp 2012). Genetic algorithms mimic biological evolution by broadly populating the stimulus space with numerous stimuli and using their elicited neural responses as a measure of fitness. The fittest stimuli in each generation are then used to define the next generation of stimuli by recombination of their features in a manner analogous to sexual reproduction (Yamane et al. 2008; Chambers et al. 2014). Genetic algorithms have the advantage of being more robust to local maxima than hill-climbing methods and more extensively sampling the stimulus space.

Iso-response Surfaces

Instead of finding the single stimulus that optimizes the firing rate, it is also useful to find the set of all stimuli which elicit the same firing rate response.

The shape of these firing rate level sets can tell us about how a sensory neuron combines stimulus dimensions. This method has been applied in diverse contexts, including studies of spectral integration in grasshopper auditory neurons and integration of photoreceptor inputs by V1 neurons (Gollisch et al. 2002; Horwitz and Hass 2012).

Optimizing Information

Instead of characterizing a neuron by its preferred or “optimal” stimulus, an alternative approach is to characterize the neuron in terms of the stimulus ensemble which its responses most reliably distinguish. This may be quantified by maximizing the mutual information between the stimuli and neural responses, and this technique was applied by Machens et al. (2005) in a study of grasshopper auditory receptor neurons.

Estimating and Comparing Models

Given an accurate model of the input-output relationship for a sensory neuron, it is possible in principle to predict the neuron's response to an arbitrary stimulus. However, estimating high-dimensional models from limited experimental data often poses a serious technical challenge. A study by Lewi et al. (2009) demonstrated that adaptively selecting stimuli to optimize expected

mutual information between neural responses and model parameters allowed fast and robust estimation of generalized linear models. Subsequent work by DiMattina and Zhang (2011) extended this idea to arbitrary stimulus-response models and also considered the problem of adaptively optimizing stimuli for comparing multiple, competing neural models. These methods were verified experimentally in a study of spectral integration in the primate inferior colliculus (Tam 2012). More recent work has considered the use of well-chosen priors to further speed convergence of receptive field estimates (Park and Pillow 2012, 2016). Optimization of sensory stimuli for model estimation and comparison have also been recently applied in vision psychophysics and cognitive science (Wang and Simoncelli 2008; Myung et al. 2013; Kim et al. 2014).

Definition

Algorithmic reconstruction of neuronal morphology is the process of parameterizing neurite branching patterns, quantifying the parameters for a given population of experimentally reconstructed neurons, and then feeding the data into an algorithm which computationally generates populations of “virtual” neurons.

Detailed Description

Background

Digitization of neuronal morphology is important for computational neuroscience because neuronal morphology affects synaptic integration and firing behavior within individual neurons as well as determining potential connectivity with other neurons (Ascoli 2002). However, experimental reconstruction techniques are still largely manual or, at best, semiautomated, requiring time and skill to accurately capture neuronal morphology. As computational models of the nervous system grow in scale with computational power, there is an increasing need for large numbers of digitized (“virtual”) morphologies. Algorithmic generation of virtual morphologies has the potential to fulfill this need.

Motoneurons, as the nervous system’s “final common pathway” of motor control (Sherrington 1906), have long been studied. These neurons exhibit extensive dendritic arborizations that may stretch over several millimeters in the spinal cord (Cullheim et al. 1987a, b) which makes their reconstruction particularly challenging. As such, the earliest forays into algorithmic generation of neuronal morphology occurred in motoneurons. In particular, one set of reconstructed motoneurons from Cullheim et al. (1987a, b) has been the basis of algorithmic generation research by multiple groups (these morphologies are available for download at neuromorpho.org).

The general process of algorithmic generation begins by parameterizing the neurite branching patterns. These parameters are statistical distributions which are then quantified from experimental reconstructions. Generation then proceeds from the soma outwards, first generating primary neurites which go on to branch or terminate according to the chosen algorithm. This process continues until all branches have terminated. The algorithmic reconstructions are then compared to the experimental reconstructions, whereupon persistent differences are explored to improve the parameterization and algorithm. As this process is repeated, the algorithmic reconstructions become more and more similar to the experimental. The ultimate goal of this line of research is the

capability of generating populations of unique morphologies which are statistically indistinguishable from the experimental population upon which they are based and which capture the natural variability of such a population.

Parameterization

Hillman (1979) was the first to propose that a set of “fundamental” parameters could be used to completely and parsimoniously describe neuronal morphology. He recognized that there are two separable aspects of neuronal morphology that must be parameterized: the branching patterns and the space-filling behavior. It is important to remember that these parameters are not scalar values, but rather statistical distributions, and also that these parameters may be intercorrelated or correlated with other local properties of the arborization.

To capture the branching patterns, Hillman proposed that every neurite tree begins with a “stem diameter” and grows for a certain “segment length” while changing diameter by “segment taper.” If the final diameter of a branch is larger than the “terminal diameter,” the branch bifurcates into two daughter branches, whose diameters are related to that of their parent by the “branch power” and whose relative diameters are determined by the “daughter ratio.” Hillman proposed that quantifying these parameters was sufficient to completely describe neurite branching patterns.

To capture the space-filling patterns, Hillman proposed that one must measure the initial direction of neurite trees and the branching angles (the angles that daughter branches make with regard to the parent branch). Since that time, it has been recognized that to capture space filling, more parameters need to be measured. Proposed additions include some measure of “meander” (how much a neurite’s direction changes as a branch extends outwards) and some measure of “tropism” (a force inducing a directionality in neurite behavior, such as an apical dendrite extending towards the pia).

Slightly different parameter sets have since been proposed and explored based on Hillman’s original fundamental parameters.

Algorithms

Burke et al. (1992) were the first to realize that parameterization of neuronal morphology could be used to algorithmically generate virtual neurite trees. Using experimentally reconstructed motoneurons (Cullheim et al. 1987a, b), their strategy was to “(1) devise a model system that can simulate dendritic trees, (2) derive the required model parameters directly from measurements of real dendrites, and (3) refine the parameter derivations or basic model assumptions, based on the degree of congruence between real and simulated dendrites” (Burke et al. 1992). Using this methodology, Burke et al. found correlations between their parameters and local diameter and path length from the soma. Marks and Burke later extended this work (2007a, b) to include space-filling parameters and the generation of entire neurons.

Ascoli and Krichmar (2000) were the first to apply the methodology in order to create entire neurons, by adding somatic and neurite trunk parameters to a software package called L-Neuron. This software package could replicate Burke et al.’s (1992) algorithm, as well as several algorithms derived more closely from Hillman’s (1979) parameterization. Ascoli et al. (2001) then went on to explore these algorithms using experimental reconstructions of several different types of neurons, including the motoneurons from Cullheim et al. (1987a, b). Donohue and Ascoli (2008) later extended this work to allow parameters to be correlated with local neurite properties (branch order, diameter, and path length from the soma). In an extensive analysis, they explored which local properties are most important for generating realistic morphologies.

Many groups have been exploring algorithmic generation of neuronal morphology, but relatively few have explicitly explored motoneurons. Torben-Nielsen et al. (2008) developed a very different sort of algorithm which they used to explore motoneuron morphology. In this algorithm, parameters are not quantified in advance, but rather the entire parameter space is explored in an evolutionary algorithm which can converge on parameter values which produce realistic morphologies.

Summary

Algorithmic generation of motoneuron morphology is a subset of general algorithmic generation of neuronal morphology. The methodology offers the promise of a deeper understanding of neuronal morphology and may eventually fulfill the need of computational neuroscientists for large numbers of realistic morphologies for use in simulations. While no algorithm has yet been capable of producing morphologies which are statistically indistinguishable from experimental reconstructions across all morphometrics, much progress has been made. The study of motoneurons is especially useful for algorithm development because several different groups have explored the same data set (Cullheim et al. 1987a, b), thus providing a basis for further improvement.

Amari Model

Roland Potthast
Department of Mathematics, University of
Reading, Reading, UK

Definition

The Amari neural field model (cf. (Amari 1975, 1977)) provides a simple field-theoretic approach to the dynamics of neural activity in the brain. The model uses excitations and inhibitions over some distance as an effective model of mixed inhibitory and excitatory neurons with typical cortical connectivities. The model is a scalar dynamical equation for the voltage or activity $u(x, t)$ of the form.

$$\begin{aligned} \frac{\partial u}{\partial t}(x, t) &= -u(x, t) \\ &\quad + \int_B w(x, y) f(u(y, t)) dy, x \in B, t \\ &\geq 0, \end{aligned} \tag{1}$$

where initial conditions $u(x, 0) = u_0(x)$, $x \in B$ are given. Here, B is our *brain*, i.e., some domain where the neural activity takes place; f is the local *activation function* or *firing rate function*; and w is the *connectivity function* which models the strength of the connectivity or signal propagation from $y \in B$ to the point x .

A common choice for the activation function has *sigmoidal shape*.

$$f(s) := \frac{1}{1 + e^{-\beta(s-h)}}, s \in \mathbb{R}, \quad (2)$$

which is monotonously growing from $f(-\infty) = 0$ to saturation $f(\infty) = 1$ for large s , where h is the *threshold* and β is a *steepness parameter*. Often, the kernel w is chosen to be homogeneous, i.e., $w(x, y) = w(x - y)$. In this case, the integral becomes a convolution integral, such that the Amari equation can be written in the form.

$$\frac{\partial u}{\partial t} = -u + w \otimes f(u). \quad (3)$$

The Amari equation provides a continuous analogue or continuous description of *neural networks*, which has become widely used in the engineering community.

Historic Background and Applications

The earliest *field models* for describing and studying neural activity dynamics go back to Beurlle (1956), investigating the proportion of active neurons in randomly connected networks, followed by work of Griffith (1963, 1965). The basis of modern field dynamical models has been the work of Cowan, Nunez, and Amari in the 1970s (see Wilson and Cowan 1972, 1973; Nunez 1974; Amari 1977). Cowan proposed an activity-based model with two distinct populations of excitatory and inhibitory subpopulations. Amari suggested a more condensed scalar model with a Mexican hat-type connectivity function, where excitation and inhibition are reflected by the changing sign of the connectivity kernel $w(x - y)$.

The Amari neural field model has been applied, e.g., to autonomous robotic behavior (Erlhagen and Bicho 2006), embodied cognition (Schöner and Dineva 2007), dynamic causal modeling (Daunizeau et al. 2009), and language processing (beim Graben et al. 2008; beim Graben and Potthast 2012); for further details, we refer to the recent tutorial by Coombes et al. (2013).

Theory

The problem (4) is an integrodifferential equation, establishing an *evolutionary dynamical system* with initial condition $u(x, 0) = u_0(x)$, $x \in B$, at time $t = 0$. For a Lipschitz continuous activation function f , *existence* and *uniqueness* of a solution u of Eq. 4 for all times and in one or several dimensions are obtained under quite general conditions based on elementary arguments and the fixed-point theorem (compare Potthast and beim Graben 2010). Over time, there has been significant activity to study the existence and uniqueness of *bumps* and *waves* in one spatial dimension when a particular homogeneous kernel $w(x - y)$ is given (see Kishimoto and Amari 1979; Ermentrout and McLeod 1993) where smooth sigmoidal firing rates are used (see also Coombes and Schmidt 2010; Oleynik et al. 2013; Coombes and Owen 2004 for more general but still rather restricted classes of functions f).

Delay Neural Field Equation and Homogeneous Kernels

Geometric singular perturbation analysis investigates the stability of static or transient solutions, and *numerical bifurcation techniques* investigate the existence and properties of bifurcation points in state or parameter spaces (compare Pinto and Ermentrout 2001a, b; Laing and Troy 2003b). For studies in two or more dimensions, we refer to Taylor (1999), Laing and Troy (2003a), Folias and Bressloff (2004), Laing (2005), Owen et al. (2007), Kilpatrick and Bressloff (2010a), and

Coombes et al. (2012). Often, the Eq. 4 is complemented by a *delay term*.

$$\frac{\partial u}{\partial t}(x, t) = -u(x, t) + \int_B w(x, y) f\left(u\left(y, y - \frac{D(x, y)}{v}\right)\right) dy, \quad (4)$$

$x \in B$, $t \geq 0$, where $D(x, y)$ is the length of the fiber between x and y and v is the finite propagation speed of signals. The above analysis for neural field equations has been extended to delay equations (see Nunez 1974; Jirsa and Haken 1997; Coombes et al. 2003; Hutt 2004; Venkov et al. 2007; Grindrod and Pinotsis 2010), including dendritic processing (Bressloff and Coombes 1997) and synaptic depression (Kilpatrick and Bressloff 2010b).

Most of the above work uses homogeneous kernels $w(x - y)$. More recent work that tackles heterogeneity (primarily using simulations) can be found in Brackley and Turner (2007), Bressloff (2012), Schmidt et al. (2009), and Coombes et al. (2012) and functional analytic results in Faugeras et al. (2008), and Potthast and beim Graben (2010). The *inverse problems* perspective for either homogeneous or nonhomogeneous kernels has been investigated by Potthast and beim Graben (2009) and beim Graben and Potthast (2009). More recently, *stochastic neural field equations* have become very popular; compare the review by Bressloff (2012).

Advantages of the Approach

The Amari neural field model provides a very concise scalar equation to model neural activity and dynamics. In contrast to microscopic models, it summarizes the activity of neurons into the activity function $u(x, t)$, which can be used to reduce the computational complexity significantly. The field-theoretic approach opens the dynamic system to mathematical analysis and beyond the range of discrete network models.

Limitations

The strength of the Amari model is its simplicity, which is at the same time its strongest limitation. It does not take into account the complex chemical and physiological processes which take place in addition to electrical dynamics in neural tissue, nor is it capable to include the different temporal scales on which these processes work and propagate.

synaptic current by processes of synaptic plasticity and they co-localize with NMDA receptors.

Detailed Description

AMPA receptors are named for the selective agonist (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) that does not bind well to other glutamate receptors. The receptor is permeable to cations and can allow Na^+ , K^+ , and Ca^{2+} to cross the membrane and has an equilibrium potential $E_{\text{AMPA}} = 0 \text{ mV}$. The permeability to Ca^{2+} is small and is not considered important for initiating signaling cascades. AMPA receptors are composed of four types of subunits, and the combination of subunits determines the kinetics and permeability to cations.

Kinetics of AMPA Receptors

Mathematical representations of AMPA currents include the time-dependent synaptic conductance, $g_{\text{AMPA}}(t)$, in the current–voltage equation:

$$I_{\text{AMPA}}(t) = g_{\text{AMPA}}(t)(V(t) - E_{\text{AMPA}}) \quad (1)$$

The time-dependent synaptic conductance represents the opening and closing kinetics of the receptor channels and may be based on a double exponential function (or a similarly shaped function).

$$g_s(t) = \bar{g}_s \left(e^{-t/\tau_1} - e^{-t/\tau_2} \right) \quad (2)$$

where τ_1 is the onset time constant ($\tau_2 < 0.1 \text{ ms}$) and τ_2 is the decay time constant ($\tau_2 < 3 \text{ ms}$) (Hestrin et al. 1990; Trussell et al. 1993; Jonas et al. 1993). AMPA currents have a faster decay than NMDA currents (Jonas and Spruston 1994) and typically have a substantially larger peak current.

Because AMPA currents are usually the dominant excitatory synaptic currents, simple representations of these currents may be the only synaptic currents included in the practice of

OR, USA

Definition

A glutamate receptor that is permeable to sodium ions and carries an excitatory synaptic current following the binding of glutamate. AMPA receptors are regulated to control the maximum

modeling neural circuits. In models with low time resolution, AMPA currents may be represented as increased currents in a single time bin without short-term temporal details. However, these simple models may contain long-term plasticity that changes the circuit dynamics over time by changing the strength of connections between neurons.

Computational Functions of AMPA Receptors

The excitatory characteristics of AMPA currents can be the main driver of activity in a network of neurons and for communication across long distances such as from the periphery to the central nervous system. Due to the short time constants of AMPA kinetics, signal transmission can carry high temporal precision. An example of this precision is found in the auditory pathway where the interaural time difference can be discerned to extreme precision (Konishi 1990).

Another consequence of the short duration of AMPA currents is that they require a large population of independent asynchronous inputs to deliver a constant depolarization to a neuron. A single AMPA synapse can deliver a fast synaptic current that is filtered by cable properties of the dendrite where the postsynaptic terminal is located (Rall 1967). But there are temporal limitations to how much filtering is possible to deliver the excitatory effect to the spike-generating zone of the postsynaptic neuron. Multiple AMPA currents located on the postsynaptic neurons can overcome this constraint if the rate of incoming spikes is high enough and well distributed in time to overlap. Thus, the synaptic dynamics of a single synaptic terminal may not have a great influence on the postsynaptic activity.

The strength of the synaptic current is not the only determinant of the efficacy of the synaptic input to generate a spike in the postsynaptic neuron. Spikes are triggered by changes in membrane potential, and the filtering properties of the neuron are critical in how the dynamics of the individual synapses are transformed into changes in postsynaptic activity.

AMPA Synaptic Dynamics

In addition to the channel kinetics, AMPA currents exhibit short-term plasticity that can result from both pre- and postsynaptic mechanisms (Zucker and Regehr 2002; Blitz et al. 2004). Presynaptic mechanisms affect the release of glutamate and can influence the peak of the current on subsequent presynaptic spikes. Postsynaptic mechanisms affect the response of AMPA receptors to the concentration of glutamate in the synaptic cleft.

AMPA currents are also involved in long-term plasticity and can be the main component of changes in synaptic strength. AMPA currents do not play a direct role in inducing long-term plasticity but reflect the changes in presynaptic release and their own response to glutamate caused by other mechanisms.

List of Abbreviations

A1	Primary auditory cortex
AC	Auditory cortex
AMPA	α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
AN	Auditory nerve
AVCN	Anteroventral cochlear nucleus
CNC	Cochlear nucleus complex
CNIC	Central nucleus of the inferior colliculus
DAS	Dorsal acoustic stria
DCIC	Dorsal nucleus of the inferior colliculus

DCN	Dorsal cochlear nucleus
DLL	Lateral lemniscus dorsal nucleus
GABA	γ -Aminobutyric acid
IAS	Intermediate acoustic stria
IC	Inferior colliculus
IHC	Inner hair cell
LCIC	Lateral cortex of the inferior colliculus
LOC	Lateral olivocochlear neurons/system
LSO	Lateral superior olive
MGB	Medial geniculate body
MGD	Dorsal division of the medial geniculate body
MGM	Medial division of the medial geniculate body
MGV	Ventral division of the medial geniculate body
MNTB	Medial nucleus of the trapezoid body
MOC	Medial olivocochlear neurons/system
MSO	Medial superior olive
NLL	Nuclei of the lateral lemniscus
NMDA	<i>N</i> -Methyl-d-aspartate
OHC	Outer hair cell
PO	Periolivary nuclei
SOC	Superior olivary complex
SPO	Superior paraolivary nucleus
VAS	Ventral acoustic stria
VCN	Ventral cochlear nucleus
VLL	Ventral nucleus of the lateral lemniscus
VNTB	Ventral nucleus of the trapezoid body

An auditory system is found in all classes of vertebrates, including fish, amphibians, reptiles and birds, and mammals. Although there are important similarities across classes, the system has evolved differently in the different groups. Even within the class of mammals, there are notable specializations, especially in echolocating mammals such as cetaceans and bats. Because one major objective in hearing research is to understand the structure and physiology of the human auditory system, this entry is restricted to an overview of the general plan of organization of the mammalian system. Insights gained from research in animals should aid in identifying the causes of hearing impairments in humans and represent an important step toward developing effective treatments.

The specific auditory stimulus consists of pressure waves arriving at the ear within a certain frequency range. This audible frequency range varies among species (e.g., humans, 0.02–20 kHz; rat, 0.25–70 kHz; mouse, 2–70 kHz; guinea pig, 0.2–45 kHz; and cat, 0.125–60 kHz) (reviewed in Malmierca 2003; Fay 1988). Within their audible range, some species, such as echolocating bats, are tuned to particular frequencies of special importance for their behavior (reviewed in Fay and Popper 1994) and are considered to be “auditory specialists” (Echteler et al. 1994).

Sound waves are transmitted mechanically through the outer and middle ear to the sensory hair cells of the organ of Corti, in the cochlear partition of the inner ear. Auditory nerve fibers transmit information about receptor potentials generated by the sensory hair cells to the brainstem (Fig. 1). In contrast to the minimum of two relay stations between the periphery and cerebral cortex in the visual and somatosensory

systems, there is a minimum of three relays in the auditory system (Fig. 2), with several stages of convergence and divergence, and at least seven levels of crossing fibers (Figs. 2 and 3), making the auditory system uniquely complicated. In the first relay center, the cochlear nuclear complex (CNC), signals carried by the cochlear nerve are channeled into a number of parallel ascending tracts (Figs. 1 and 2), each with a particular course and destination and each presumably serving a different function (Fig. 3). Some of these terminate in a collection of nuclei in the pons known as the superior olivary complex (SOC). Ascending auditory tracts from both the CNC and the SOC converge on the inferior colliculus in the midbrain (Figs. 2, 3, and 8). From the midbrain upward, the auditory pathway is often divided into core or “lemniscal” projections with a clear tonotopic organization and belt or “nonlemniscal” projections where tonotopy is less sharp or absent (for review, see Malmierca 2003; Malmierca and Hackett 2010).

Anatomy and Physiology of the Mammalian Auditory System, Fig. 1 Afferent and efferent innervation of the cochlear epithelium. Several type I afferent fibers converge onto single IHCs, while a single type II afferent fibers innervate several OHCs. Type I fibers terminate in the AVCN, and type II fibers terminate on the granule cell regions (*GrC*) and marginal shell areas of the VCN and

DCN. The efferent MOC innervate the OHCs, and the efferent LOC innervate IHCs (cf. Figure 19) (Modified after Brown et al. 1988). The Auditory Nerve

The auditory nerve (AN) is made of both *afferent* and *efferent* fibers (for review, see Slepecky 1996). The afferent fibers transmit impulses from the organ of Corti to the cochlear nuclear complex, while the efferent fibers convey impulses from the superior olivary complex to the organ of Corti (Fig. 1). There are two subtypes of

afferent fibers: myelinated and unmyelinated fibers (Fig. 1). The myelinated (type I) fibers are relatively thick and originate from bipolar spiral ganglion cells that innervate the inner hair cells (IHCs). The unmyelinated (type II) fibers are thinner and arise from small, pseudounipolar spiral ganglion cells that innervate the outer hair cells (OHCs). About 90–95% of auditory nerve fibers are type I (Fig. 1); each type I fiber terminates on a

single IHC. The type II fibers constitute only about 5% of all auditory nerve fibers (Fig. 1). As opposed to type I, type II fibers are highly branched, and a single fiber forms synapses with many (6–100) OHCs.

Three types of type I fiber have been characterized based on morphological features that correlate with their spontaneous activity and threshold sensitivity (Liberman et al. 1990). Fibers with a low threshold and a high spontaneous firing rate have the larger diameter and terminate on the pillar side of the IHC, whereas fibers with a high threshold and a low spontaneous firing rate are thinner and terminate on the modiolar side.

The efferent fibers of the olivocochlear system belong to the descending auditory pathways (Fig. 1). They can be divided into two groups: the lateral efferent system (lateral olivocochlear system) that innervates auditory nerve fibers near their synapses with IHCs and the medial efferent system (medial olivocochlear system) that innervates the OHCs (Warr 1992).

The Cochlear Nuclear Complex

The cochlear nucleus complex is situated laterally and superficially in the brainstem (CNC, Figs. 1–5) and is the first relay center for ascending auditory information. It is the site of termination of all auditory nerve (AN) fibers (Ryugo and Parks 2003). The CNC consists of a ventral cochlear nucleus (VCN) and a dorsal cochlear nucleus (DCN). The VCN is subdivided by the cochlear nerve root into anteroventral (AVCN) and posteroventral (PVCN) parts. The DCN curves around the inferior cerebellar peduncle in the floor of the lateral recess of the fourth ventricle. The axons of CNC projection neurons leave the complex via the three primary pathways to reach higher auditory structures: the dorsal, intermediate, and ventral acoustic striae (DAS, IAS, and VAS, respectively). The VAS is usually referred to as the trapezoid body (Figs. 2 and 3). The projections are largely tonotopically organized, and neurons within an isofrequency lamina of the CNC project to a corresponding

isofrequency lamina in higher-order centers. The right and left CNC are also interconnected by fibers of glycinergic commissural neurons as described below (for review, see Cant and Benson 2003). In addition to its ascending inputs from the AN, the CNC receives descending projections from the auditory cortex, the inferior colliculus; the ventral complex of the lateral lemniscus; and the superior olivary complex (see Malmierca 2003). A large proportion of the latter fibers may be inhibitory, glycine and/or GABA being the transmitters, but there are also excitatory descending fibers, e.g., collaterals of the cholinergic olivocochlear bundle (Osen et al. 1984). The CNC also receives some projections from non-auditory brain structures.

Primary Afferents

Each AN fiber bifurcates into an ascending branch, which supplies the AVCN, and a descending branch, which supplies the PVCN and DCN (Fig. 1). The anatomical distribution of the primary fibers forms the basis for the laminar tonotopic organization of the three subnuclei observed electrophysiologically (for review, see Ryugo and Parks 2003). Type I fibers supply all parts of the CNC except the superficial granule cell areas and the molecular layer of the DCN (Fig. 1). Two basic types of terminals are found: large, axosomatic endings called “endbulbs of Held” and small boutons. The endbulbs of Held arise from the ascending branches, while small boutons arise from loosely ramifying collaterals of both ascending and descending branches. The type II fibers innervate areas rich in granule cells and appear to supply the marginal shell of the VCN (Fig. 1) (for review, see Ryugo and Parks 2003).

Ventral Cochlear Nucleus

Five main neuronal types are recognized in the VCN based on patterns of Nissl staining, dendritic arborization, and main axonal projections: spherical bushy, globular bushy, octopus, multipolar

Anatomy and Physiology of the Mammalian Auditory System, Fig. 3 Projecting cell types of the CNC and their corresponding physiological responses (Modified after Moore and Osen 1979). For abbreviations, see list. Abbreviations in the figure: *CIC* Central nucleus of the

inferior colliculus, *cic* Commissure of the inferior colliculus, *ll* lateral lemniscus, *MTz* Medial nucleus of the trapezoid body, *PnC* Pontine reticular nucleus, caudalis, *SPO* Superior paraolivary nucleus

(or stellate), and small cells (Figs. 3–5; Osen 1969; Brawer et al. 1974).

The spherical bushy cells are found rostrally in the AVCN, the globular bushy cells lie centrally on both sides of the nerve root in the caudal AVCN and the rostral PVCN, and the octopus

cells are found caudally in the PVCN. The spherical bushy, globular bushy, and octopus neurons (Fig. 3) have non-tapering dendrites that end in bushy-like formations, but they differ with regard to the appearance of the terminal bush, the number of root segments, and the relative length of the

Anatomy and Physiology of the Mammalian Auditory System,

Fig. 4 Diagram of the planar (T-stellate) and radiate (d-stellate) cells in the VCN and their projections to the DCN. Planar cells have frequency-specific projections, while radiate cells have across frequency projections (Figure kindly provided by Dr. D. K. Ryugo. Reproduced from Doucet and Ryugo 1997). For abbreviations, see list. Abbreviations in the figure: AN auditory nerve, DC Dorsal cochlear nucleus, LTz Lateral nucleus of the trapezoid body, VCA Anteroventral cochlear nucleus, VCP Posteroventral cochlear nucleus

stem dendrites. The spherical bushy cells receive a small number of large axosomatic terminals, the endbulbs of Held (for review, see Ryugo and Parks 2003), and have the so-called primary-like responses to pure tone stimulation, similar to those of the auditory nerve fibers (Young et al. 1988; Young and Davis 2002). The spherical bushy cells (Fig. 3) project bilaterally to the medial superior olive and to the ipsilateral lateral superior olive (Cant and Benson 2003). Globular bushy cells receive a larger number of distinct inputs than do the spherical bushy cells, including small (or “modified”) endbulbs. In response to pure tone stimulation, they exhibit a firing pattern known as “primary-like with notch.” The globular bushy cells (Fig. 3) project to the ipsilateral lateral nucleus of the trapezoid body and the contralateral medial nucleus of the trapezoid body. Axons from both globular and spherical bushy cells

course ventrally in the trapezoid body. The patterns of their AN input, along with unique cell membrane properties, make these cells capable of transmitting precise temporal information necessary for both high- and low-frequency sound localization (Young et al. 1988; Young and Davis 2002). The octopus cells (Fig. 6) receive small boutons from collaterals arising from the descending branch of the AN. They respond to a tone burst with a single spike and so have been called onset units (Young et al. 1988; Young and Davis 2002). Their main projection is to the superior paraolivary nucleus on both sides and to the contralateral ventral complex of the lateral lemniscus, and their axons course dorsally, looping over the restiform body in the intermediate acoustic stria (Wickesberg and Oertel 1988; for review, see Cant and Benson 2003). Their function is still unclear, but it has been suggested that they encode

Anatomy and Physiology of the Mammalian Auditory System,

Fig. 5 Synaptic endings containing glutamate, glycine, and GABA in the rat dorsal cochlear nucleus. Synaptic endings and of the known (*solid lines*) and putative (*dashed and dotted lines*) neuronal sources of excitatory and inhibitory endings onto pyramidal (FC), vertical (VC), and cartwheel (CWC) cells (Figure kindly provided by Dr. M. E. Rubio. Reproduced from Rubio and Juiz 2004)

the pitch period in their temporal firing patterns (Oertel 1999).

The *multipolar* and *small* cells are present throughout the VCN (Figs. 3 and 4). The small cells are most abundant around the peripheral margins of the nucleus deep to the superficial granule cell layer. A large collection of small cells located dorsolaterally in a superficial location forms the *small cell cap* of the VCN (Osen 1969). This is particularly conspicuous in cat. The *multipolar cells* (Figs. 3 and 6) possess moderately branched, tapering dendrites which are contacted by small boutons from many primary afferent fibers. Two types of multipolar cell have

been described (Fig. 3): type I, also referred to as T-stellate (mouse) and planar (rat), and type II, also referred to as d-stellate (mouse) or radiate (rat).

Multipolar type I cells (Figs. 3 and 4) have oriented dendritic arbors and project to the periolivary region of the superior olivary complex via the trapezoid body, the nuclei of the lateral lemniscus, and the central nucleus of the inferior colliculus through the lateral lemniscus (Adams 1979; Cant and Benson 2003; Malmierca et al. 2005). They also give rise to frequency-specific collaterals within the VCN and DCN (Lorente de Nó 1981). These multipolar neurons exhibit a

Figure kindly provided by Dr. E. Friauf).

Abbreviations in the figure: DMPO Dorsomedial periolivary region, LPO Lateral periolivary zone, LTz Lateral nucleus of the trapezoid body, MTz Medial nucleus of the trapezoid body, PO Periolivary regions, SPO Superior paraolivary nucleus, tz Trapezoid body (or ventral acoustic stria); VTz Ventral nucleus of the trapezoid body

“chopper” response to tone bursts with regularly repeated firing. They may be specialized for conveying frequency-specific excitatory information about complex acoustic stimuli such as speech.

Multipolar type II cells (Figs. 3 and 4), also known as commissural neurons, have non-oriented dendritic arbors. They project

to the contralateral CNC via the dorsal acoustic stria (Smith and Rhode 1989; Oertel et al. 1990; Doucet and Ryugo 1997). They also emit extensive (probably broadly tuned) collaterals within the ipsilateral VCN and DCN. They are the only known inhibitory (glycinergic) projection neurons of the CNC (Osen et al. 1990; Doucet et al. 1999)

and respond to pure tone stimulation with an “on-chop” pattern (Smith and Rhode 1989).

The *small cells* are abundant in the marginal shell of the VCN, which is composed of the “granule cell layer” and the subjacent “cap area”. The granule cell layer is continuous over the free surface of the CNC and forms a lamina partly separating the VCN and DCN (Mugnaini et al. 1980a, b; for review, see Cant and Benson 2003). In the DCN, the granule cell layer is covered superficially by a molecular layer. The granule cell axons project as parallel fibers (Fig. 5) to the molecular DCN layer (Mugnaini et al. 1980a, b). The cap area is small but still distinguishable due to its contingent of small cells, many of which show glycine- and/or GABA-like immunoreactivity (for review, see Cant and Benson 2003). The cap is supplied by both type I and type II fibers (Fig. 1), and at least in cat, nearly all type I auditory nerve fibers that innervate the cap have low spontaneous rates (for review, see Ryugo and Parks 2003). The marginal shell also receives descending input. Its cells show a wide dynamic range (Ye et al. 2000) and have a large diversity of projections (Adams 1979; Malmierca et al. 2002, 2005; Ye et al. 2000). The available electrophysiological studies suggest that they form part of a feedback gain control system made up of the cochlea, cochlear nuclear complex, medial olivocochlear system, and outer hair cells (Ye et al. 2000).

Cochlear Root Neurons (Fig. 3). The CNC of rodents contains a population of large cells scattered in the cochlear nerve root, between the main body of the VCN and the glial Schwann-cell border of the AN. It has been suggested that these root neurons participate in the acoustic startle reflex (Sinex et al. 2001).

Dorsal Cochlear Nucleus

The DCN varies from being markedly laminated in rodents and carnivores, where it resembles the cerebellar cortex, to appearing nonlaminated in humans (but see Rubio et al. 2008) and some bat species; it is virtually absent in some cetaceans. The three superficial layers of the DCN are related

to the morphology of the principal pyramidal (fusiform) cells (Figs. 3 and 5). The spiny apical dendritic arbor of pyramidal cells occupies layer 1 together with granule cell axons and several other types of interneurons (Fig. 5, see below). Pyramidal cell bodies define layer 2, and their aspiny basal dendritic arbors comprise layer 3. Pyramidal cell dendritic arbors are flattened across the long, frequency gradient axis of the DCN (see, e.g., Cant and Benson 2003; Malmierca 2003). The highest degree of flatness and mutually parallel orientation is found in the basal arbor, which is supplied by primary afferent fibers in a strictly tonotopic manner.

The pyramidal cells are the main projection neurons of the DCN, supplying fibers to the contralateral IC via the DAS (Fig. 3). In addition, some have a direct projection to the medial division of the medial geniculate body (Malmierca et al. 2002). The deepest layer of the DCN contains two categories of cells based on their size, the giant cells which project to the contralateral IC through the DAS and smaller glycinergic tuberculoventral interneurons (Fig. 5). Pyramidal and giant cell excitatory responses are more strongly influenced by their inhibitory inputs than are those of other projection neurons in the CNC and have been classified as types III and IV (Oertel and Young 2004). The type IV units have been found to be sensitive to spectral notches created by the pinna, which may be important cues for localizing sounds. DCN projection neurons receive and respond not only to auditory information but also to somatosensory inputs from muscle proprioceptors in and around the pinna. This innervation has led to speculation that the DCN may be involved in coordinating pinna orientation with localization cues found in the different spectra of sounds located at different points in space. In fact, bilateral lesions of the DAS in cats result in reduced accuracy in head orientation responses to broadband sounds, particularly in elevation (reviewed in Young and Davis 2002).

DCN possesses a large number of interneurons that may be divided into two systems: the tuberculoventral system and the granule cell system (Fig. 5). The *tuberculoventral system*

reciprocally interconnects the DCN and VCN. It contains both frequency-specific and diffuse projections (Malmierca 2003). The frequency-specific projection from the DCN to the VCN originates from small interneurons, a subset of the glycinergic “vertical cells” (Fig. 5). A separate set of vertical cells with only local collaterals contain both GABA and glycine, the relative amounts of which vary among species. They are located between the basal pyramidal cell dendrites in layer 3, have flattened dendritic arbors, and provide the DCN and VCN with a tonotopically organized inhibition. One projection from the VCN to the DCN is made up of the collaterals of type I multipolar cells described above and probably is excitatory and tonotopic. An inhibitory projection arises from axonal collaterals of the glycinergic commissural (type II) cells. The vertical cells of the DCN provide inhibition over a narrow frequency range, whereas the on-chop, type II stellate cells generate inhibition over a wide frequency range.

The granule cell system includes two types of excitatory cells: granule cells and unipolar brush cells and three types of inhibitory cells: the GABAergic Golgi and stellate cells and the glycinergic cartwheel cells (Fig. 5; Oertel and Young 2004; Rubio and Juiz 2004). The granule cells receive direct excitatory input from many sources including the somatosensory system and inhibitory inputs via the Golgi cells. The granule cell axons contribute parallel fibers to the molecular layer. The unipolar brush cells seem to represent a device for feedforward excitation to the mossy fiber pathways, while the stellate cells and cartwheel cells provide feedforward inhibition to the pyramidal cells (Rubio and Juiz 2004; Fig. 5).

The Superior Olivary Complex

The superior olivary complex (SOC) comprises a group of nuclei in the caudal pons (Figs. 2 and 6). Three main nuclei are consistently identified: the lateral superior olive (LSO), the medial superior olive (MSO), and the medial nucleus of the trapezoid body (MNTB). These three nuclei are

surrounded by more diffusely organized cellular areas, collectively referred to as the periolivary region (PO) (Adams 1983; Osen et al. 1984; Schofield and Cant 1991). The LSO and MNTB are well developed in both the rat and cat, while they are relatively small in human. In contrast, the MSO is small in the rat but is prominent in both the cat and human (Fig. 6). These differences appear to be related to the ability to use specific frequency cues for directional hearing. The MSO extracts the information about interaural timing differences that is available in low-frequency sounds. Together, the LSO and MNTB detect interaural intensity differences generated by high-frequency sounds.

Lateral Superior Olive

The LSO consists of layers of flattened multipolar neurons (principal cells) with their dendrites oriented perpendicular to its long axis, which is curved into an S-shape. The LSO is tonotopically organized with low frequencies represented laterally and high frequencies, medially. In addition to the principal cells, other, less abundant, neuronal types are also present (Rietzel and Friauf 1998). In some species, neurons of the lateral olivocochlear system lie within the LSO.

The LSO receives direct input from the AVCN on the ipsilateral side and indirect input from the AVCN on the contralateral side (Fig. 6). The ipsilateral input derives from spherical bushy cells and is excitatory. Globular bushy cells in the contralateral AVCN project to the MNTB ipsilateral to the LSO. The MNTB, in turn, sends an inhibitory (glycinergic) input to the LSO (Fig. 6). Multipolar type I neurons from the AVCN also innervate the LSO (reviewed in Helfert and Aschoff 1997; Thompson and Schofield 2000).

The LSO projects to the central nucleus of the inferior colliculus bilaterally (Figs. 2 and 6). Most of the ipsilaterally projecting cells are inhibitory (glycinergic), while the contralaterally projecting cells are glycine-negative and presumably excitatory. The LSO also innervates the dorsal nucleus of the lateral lemniscus bilaterally (Fig. 2).

Medial Nucleus of the Trapezoid Body

Cells of the MNTB are situated among fascicles of fibers in the trapezoid body (Figs. 2 and 6). The principal cells resemble the globular bushy cells of the AVCN, whereas non-principal (marginal) cells have a multipolar appearance (Fig. 6; Morest 1968; Banks and Smith 1992; Sommer et al. 1993).

The MNTB receives input from the globular bushy cells in the contralateral VCN (Fig. 2). These cells give rise to thick axons that terminate on the principal cells in the MNTB as large axosomatic calyces of Held (1893) in a one-to-one relationship. These calyces provide a fast and secure relay of information from the CNC to the MNTB and from there to the LSO. They constitute the largest synaptic terminals in the mammalian brain. The responses of cells in the MNTB to acoustic stimuli show a sharp onset spike that is also characteristic of the globular bushy cells.

In addition to its projection to the LSO, the MNTB projects to the ipsilateral MSO as well as other parts of the ipsilateral SOC and the dorsal portion of the ventral complex of the lateral lemniscus, providing a source of widespread glycinergic inhibition.

The microcircuitry and neurochemistry of the LSO and MNTB suggest that a major function of the MNTB is to transform excitatory contralateral input into ipsilateral inhibition, allowing the LSO to faithfully encode interaural intensity differences in the high-frequency range of audition (for review, see Kopp-Scheinflug et al. 2008).

Medial Superior Olive

The MSO lies between the LSO and the MNTB (Fig. 6) and is populated by two types of cells: principal and non-principal or marginal cells. The bipolar principal cells are organized into a transversely oriented row, with their dendrites extending in the medial and lateral directions. The multipolar non-principal cells are scattered

among these dendrites and are much less numerous (Smith 1995). The MSO is tonotopically organized with low-frequency tones represented dorsally and high-frequency tones ventrally, although most of the nucleus appears to be devoted to low frequencies (Guinan et al. 1972).

The MSO receives direct, excitatory input from spherical bushy cells in the AVCN bilaterally (Fig. 6; for review, see Malmierca 2003), but these inputs remain segregated on the cell surface, such that the lateral dendrites receive input from the ipsilateral side, while the medial dendrites receive input from the contralateral side (Smith 1995). A rostrocaudal organization of the axons is reminiscent of the required input configuration in the Jeffress model for sound localization. The direct bilateral input suggests that the MSO neurons are ideally suited to measure interaural phase or time differences (Joris et al. 1998).

The MSO also receives inhibitory inputs, mostly glycinergic, from the medial and lateral nuclei of the trapezoid body on the same side. The latter may also provide GABAergic inhibitory input (Smith 1995). The principal cells project to the inferior colliculus and to the ipsilateral dorsal nucleus of the lateral lemniscus (Fig. 8).

Superior Paraolivary Nucleus

A fourth distinct nucleus in the SOC of rodents, the so-called superior paraolivary nucleus (SPO), is found in the dorsomedial part of the complex (Fig. 6; Osen et al. 1984; Schofield and Cant 1991; Schofield 1995). It consists of GABAergic multipolar cells, which are the largest in the SOC, and receives inputs from octopus and multipolar cells in the contralateral VCN, from multipolar cells in the ipsilateral VCN, and a substantial glycinergic input from the MNTB on the same side. SPO projects to the ipsilateral IC (Schofield 1995) and may represent a hyperdevelopment of periolivary cells with a similar projection, present in smaller numbers in other mammals (Adams 1983). It appears that the SPO neurons are well suited for the analysis of temporal features of

complex sounds and stimulus features across broad frequency ranges (Dehmel et al. 2002; Kulesza et al. 2003).

Periolivary Nuclei

The PO contains several distinct types of neurons with different projection patterns (Adams 1983; Osen et al. 1984). Neurons in the PO areas receive input from VCN bilaterally, the lateral areas, from the ipsilateral side, and the medial areas, from both sides (Fig. 6). Certain parts of the PO also receive input from the ipsilateral MNTB (probably inhibitory), from the ipsilateral inferior colliculus (probably excitatory), and from the dorsal nucleus of the lateral lemniscus (probably inhibitory).

PO cells project either to the cochlea, the CNC, or the IC, but individual cells do not appear to project to all three structures (Adams 1983). The ventral nucleus of the trapezoid body (VNTB) is a PO region situated ventral to the MNTB and is of particular interest because it may be involved in the activation of the olivocochlear neurons (Rajan 1990). It is strategically situated at the intersection of ascending projections from the CNC and descending projections from the IC. The VNTB receives major afferent projections from the contralateral VCN, the ipsilateral PVCN (Smith et al. 1991; Thompson and Schofield 2000), and the marginal shell in the AVCN from both sides (Ye et al. 2000). It is the major target in the SOC for the descending projections from the IC.

The Nuclei of the Lateral Lemniscus

The nuclei of the lateral lemniscus (NLL) is made of two distinct functional systems (Fig. 2), a monaural *ventral* (VLL) and a binaural *dorsal* (DLL) system (Covey and Casseday 1991). There are connectional, neurochemical, and physiological properties which are unique to each system (Covey and Casseday 1991; Malmierca et al. 1998).

The Ventral Nucleus of the Lateral Lemniscus: The Monaural System

The VLL consists of groups of neurons embedded within the part of the lateral lemniscus, located between the SOC and DLL (Fig. 2). It receives its inputs mainly from the contralateral ear via the contralateral VCN and ipsilateral MNTB (Fig. 2). VLL neurons exhibit a variety of shapes and sizes in Nissl-stained sections, and most of them project to the ipsilateral IC. The majority of cells in the ventral part of the complex are glycine and/or GABA (Riquelme et al. 2001).

In vitro, some VLL neurons show an onset firing pattern and a nonlinear current-voltage relationship, while others exhibit a linear current-voltage relationship and other firing patterns (Wu 1999; Zhao and Wu (2001)). Similar differences have also been found in in vivo studies (Zhang and Kelly 2006a, b). The VLL neurons are suitable for encoding temporal events (Covey and Casseday 1991).

The Dorsal Nucleus of the Lateral Lemniscus: The Binaural System

The DLL receives input from both ears, and it projects both to ICs and to its counterpart on the opposite side through the commissure of Probst (Fig. 2). The DLL plays an important role in functions dependent on binaural processing such as sound localization.

Several neuronal types have been described, depending on the species and the criteria used for cell classification. Regardless of the morphological type, all cells have similar membrane properties with a sustained series of regular action potentials produced by the injection of positive current.

Generally speaking, the DLL receives collaterals from afferent fibers that also innervate the IC (Fig. 8). Thus, DLL receives contralateral inputs from the ventral cochlear nucleus and DLL, ipsilateral input from the medial superior olive, superior paraolivary nucleus and VLL, and bilateral inputs from the lateral superior olive. The DLL projection to the IC is laminar and bilateral, with a

predominant projection to the contralateral IC. Most DLL cells are GABAergic and therefore have an inhibitory influence on the IC.

The Inferior Colliculus

The inferior colliculus (IC) is the principal auditory nucleus in the midbrain and is characterized by a massive convergence of inputs from lower and higher auditory centers as well as from non-auditory structures (Figs. 2 and 7; Irvine 1992; Malmierca 2003; Casseday et al. 2002; Loftus et al. 2008). The IC is divided into a central nucleus (CNIC) surrounded by cortical regions

(Fig. 7). These collicular cortices include a dorsal cortex (DCIC) that covers the CNIC dorsally and caudally, a lateral cortex (LCIC) that covers it laterally, and a rostral cortex (RCIC) that covers it rostrally (Loftus et al. 2008; Fig. 8).

Neurons in the CNIC tend to be most strongly influenced by lower auditory centers, while neurons in the DCIC and RCIC tend to be most strongly influenced by the descending pathways and commissural inputs. The LCIC (and probably the RCIC) receives both auditory and nonauditory (e.g., somatosensory) inputs.

In addition, to its intrinsic and commissural fiber systems (Malmierca et al. 1995; Saldaña and Merchán 1992), the IC provides the major ascending projections to the MGB as well as descending projections to the SOC and the CNC (Oliver et al. 1999; Malmierca et al. 1996; Peruzzi et al. 1997; Ito and Oliver 2012; Cant and Benson 2007).

The Central Nucleus of the Inferior Colliculus

The CNIC is distinguished by layers of cells and fibers organized into “fibrodendritic laminae” (Oliver and Morest 1984; Faye-lund and Osen 1985; Malmierca et al. 1993). These consist of a parallel organization of afferent lemniscal fibers and neurons with flattened dendritic arbors and constitute the structural basis for the tonotopic organization of the IC (Schreiner and Langner 1997; Malmierca et al. 2008; Fig. 9).

The CNIC is composed of two main neuronal types: disk-shaped or flat neurons and stellate or less flat neurons (Oliver and Morest 1984; Malmierca et al. 1993). These neurons differ in several respects, including the thickness, branching pattern and orientation of their dendritic arbor, and their location with regard to the laminae (Fig. 10). The flat neurons lie parallel to the ascending fibers and form laminae that are mostly one cell thick, about 40–70 μm (Faye-Lund and Osen 1985; Malmierca et al. 1993). These laminae are separated by interlaminar compartments that are populated by the stellate neurons. IC neurons show complex functional

Anatomy and Physiology of the Mammalian Auditory System, Fig. 7 Subdivisions of the inferior colliculus in the rat and cat. The low-frequency representation in the central nucleus (CIC) is expanded in cat and contracted in rats, while the size of the ventrolateral nucleus (VLN) (layer 3 of LCIC) is expanded in rat and contracted in cats. properties, and there is no simple correlation between physiological response properties and morphological classifications (Sivaramakrishnan and Oliver 2001).

The CNIC receives *ascending afferent projections* (Fig. 8) that originate in the AVCN, PVCN, and DCN bilaterally (although mainly contralaterally); the VLL and MSO ipsilaterally; and the DLL and LSO bilaterally (Malmierca 2003; Cant and Benson 2006). These inputs are tonotopically organized and tend to show a “banded” pattern of projections with dense bands (about 200 μm thick) parallel to the iso-frequency fibrodendritic laminae. The terminal fields of the various ascending projections may also vary in their distribution along the main axis of the IC. For example, in the dorsomedial parts of the laminae, the axons from the DCN do not overlap with afferents from the LSO. The CNIC projects to the ventral division of the MGB in a

tonotopic manner (Fig. 10), largely to the ipsilateral side but also with a crossed component. A majority of neurons use glutamate as the neurotransmitter, but about a quarter of the cells in the CNIC are GABAergic (Merchán et al. 2005), and some of these project to the MGB, making short-latency, monosynaptic inputs (Peruzzi et al. 1997).

IC neurons possess NMDA and AMPA receptors as well as GABA_A, GABA_B, and glycine receptors (reviewed in Kelly and Caspary 2005). Studies using microiontophoresis *in vivo* have demonstrated that the AMPA receptors regulate the onset response. Both AMPA and NMDA are involved in the maintenance of the response for the duration of the stimulus, and both GABA and glycine inhibit IC neurons and shape different temporal, spectral, and binaural properties (e.g., LeBeau et al. 2001; reviewed in Kelly and Caspary 2005). Neurons in the IC show a variety

of frequency response areas that include both V-shaped and non-V shaped types (LeBeau et al. 2001; Palombi and Caspary 1996). Binaural responses are generally classified as suppression,

summation, or mixed. The laminae of the CNIC contain a highly organized representation of both spectral and temporal parameters (for review, see Schreiner and Langner 1988).

The Dorsal Cortex of the Inferior Colliculus

The DCIC covers the dorsomedial and caudal aspects of the CNIC (Figs. 7 and 9b) and is made of three layers (Faye-Lund and Osen 1985). Layer 1 (the most superficial layer) is a thin fibrocellular capsule that wraps the entire surface of the IC including the LCIC. It contains scattered, small, flattened neurons. Layer 2 is slightly thicker and contains mostly small- and medium-sized multipolar neurons. Layer 3 includes a heterogeneous group of multipolar neurons that vary in soma size and shape and in their dendritic orientation. A distinct feature of neurons in DCIC (and also LCIC) is that they contain the neuromodulator nitric oxide, a fact that may explain some of the long-term potentiation and neuronal plasticity observed in some IC neurons (Zhang and Wu 2000).

The ascending input from lower auditory centers to the CNIC encroaches upon the DCIC, as do the intrinsic projections (Saldaña and Merchán 1992; Malmierca et al. 1995). In addition, the DCIC receives descending input bilaterally that originates largely from the primary AC. This projection may generate long-lasting changes in the neuronal responses of the IC. The DCIC projects to the dorsal division of the MGB (Winer 1985).

The Lateral Cortex of the Inferior Colliculus

The LCIC covers the CNIC laterally (Fig. 7) and ventrally (Loftus et al. 2008) and is made up of three layers (Faye-Lund and Osen 1985; Loftus et al. 2008). Layer 1 is a continuation of the fibrodendritic capsule of the DCIC. Layer 2 is composed of small- and medium-sized neurons that are partly aggregated into dense clusters rich in acetylcholinesterase and GABA. Layer 3 of the ECIC constitutes its largest part and appears to continue also into the non-stratified rostral cortex. In addition to auditory inputs, the LCIC receives somatosensory input from spinal cord, dorsal column nuclei, and spinal trigeminal nuclei in the cat (Zhou and Shore 2006). Neurons in the LCIC

appear to have relatively broad somatosensory receptive fields in addition to auditory responses, which are also broadly tuned (Aitkin et al. 1978). The multisensory integration in the LCIC mirrors similar types of function at higher levels of the “extralemniscal” auditory pathway. Although the functions of the LCIC are not known, it may be a major source of binaural cues for gaze control in the superior colliculus (King et al. 1998), and it is very likely that LCIC plays an important role in providing auditory input to visual-motor areas that direct the head and eye movements involved in gaze initiation. A second role of the LCIC may be in multisensory integration, distinct from the “classical” auditory role of the central nucleus. Finally, the CNIC and LCIC differentially activate the medial and lateral olivocochlear system (Ota et al. 2004).

The Rostral Cortex of the Inferior Colliculus

The rostral cortex (RCIC) is adjacent to the anterior CNIC (Fig. 9b) and includes the largest multipolar cells in the IC. There are also small- and medium-sized multipolar neurons (Faye-Lund and Osen 1985; Malmierca et al. 1993). Like the LCIC and DCIC, the RCIC receives input from the cerebral cortex as well as from nonauditory structures (for review, see Malmierca 2003). The RCIC projects to the dorsal and medial divisions of the MG (Fig. 2). The functional role of RCIC neurons is still unknown, although recent studies have demonstrated that many neurons in this region (and in other cortical regions) may be specialized for detecting novel sounds (Malmierca et al. 2009).

The Medial Geniculate Body

The principal auditory nucleus in the thalamus is the medial geniculate body (MGB), which is also the last opportunity for subcortical processing in the ascending auditory pathways (Fig. 2). The MGB is divided into three major divisions named relative to their locations within the

complex: the ventral (MGV), dorsal (MGD), and medial (or magnocellular) (MGM) divisions (Figs. 11 and 12). Additional subdivisions are also recognized in some species, usually representing smaller domains within each of the major subdivisions. Physiological studies have shown that the caudal part of the reticular thalamic nucleus (Fig. 2) is also a part of the auditory pathway (Cotillon et al. 1999; Yu et al. 2009). It provides the MGB with an inhibitory GABAergic input (Bartlett and Smith 1999; Yu et al. 2009).

The main source of ascending projections to the MGB is the IC (Figs. 2 and 10), but other inputs include the thalamic reticular nucleus and auditory subcollicular nuclei, including the SOC, NLL, and CNC, challenging the idea that the IC is an obligatory relay station (Malmierca et al. 2002). Ascending fibers enter the structure medially through the brachium of the IC and terminate among neurons in each subdivision. Connections

with auditory cortex pass through the posterior limb of the internal capsule, and, for the most part, these connections are reciprocal.

The Ventral Division of the Medial Geniculate Complex

The MGV contains bi-tufted principal neurons that tend to be arranged in rows with oriented dendritic fields (Fig. 12a–c; Winer et al. 1999). These neurons are glutamatergic, and most of them are immunoreactive for parvalbumin (Jones 2007). In the cat, a quarter of the neurons in the MGV are GABAergic interneurons, but these are absent in rodents and bats (Winer and Larue 1988). The MGV neurons are well tuned to frequency, exhibiting low-threshold short-latency responses to tones and complex sounds. They

Anatomy and Physiology of the Mammalian Auditory System, Fig. 10 Schematic diagram of the basic circuitry in the IC. Large GABAergic neurons (1) receive excitatory inputs on their somata, send their axons to the MGB, and inhibit tufted or stellate neurons in the MGB. Small GABAergic neurons (2) do not project to MGB.

Glutamatergic neurons (3, 4) project to the MGB and lack the dense VGLUT2 axosomatic inputs. Red puncta indicate excitatory glutamatergic terminals. Blue puncta indicate inhibitory (GABAergic and glycinergic) terminals (Figure kindly provided by Dr. D. L. Oliver. Reproduced from Ito and Oliver 2012)

immunostained for calbindin, visualized with Cy-2. (e) Overlay images from (a and c). (f) Overlay images from (b and d). Scale bar = 500 μ m (Figure kindly provided by Dr. Daniel Llano. Adapted from Lu et al. 2009). Abbreviations in the figure: *PIL* Posterior intralaminar nucleus, *PP* Peripeduncular nucleus

are sensitive to both interaural time and intensity differences.

The MGCV receives its ascending inputs primarily from the ipsilateral CNIC (Fig. 10),

(Malmierca 2003; Jones 2007). These projections arise from both glutamatergic and GABAergic neurons (Bartlett and Smith 1999; Ito and Oliver 2012). MGCV neurons project mainly to layers III

Anatomy and Physiology of the Mammalian Auditory System,

Fig. 12 Camera lucida drawings of neurobiotin-labeled cells of the rat MG. Tufted cells populate the MG. Cells with two distinct morphologies, tufted and stellate, populate MGD. Cells (d and e) and cells (f and g) are typical examples of MGD tufted and stellate cells, respectively. The dendritic trees of these cells appear similar regardless of the plane of section. Magnocellular neurons populate the MGM (Figure kindly provided by Dr. Philip Smith (some parts reproduced from Bartlett and Smith 1999)). Abbreviations in the figure: SC supragenulate nucleus

and IV of the primary (core) areas of the auditory cortex.

The Dorsal Division of the Medial Geniculate Complex

The MGD is generally characterized by a lower cell-packing density than the MG, and it lacks a laminar organization. At least two subdivisions are clearly recognized on the basis of architectonic variations and connections in most species (Burton and Jones 1976; Winer 1985). The most common neuronal type is the radiate cell (Fig. 12f–g). These have radially symmetric dendritic fields with a simple branching pattern. Tufted cells (Fig. 12a–c) are also present and

tend to form thin sheets. Finally, there is a small population of small stellate cells. Compared to the MG, parvalbumin immunoreactivity is reduced in the MGD, but there is a relative increase in the numbers of calbindin-positive cells (Jones 2007). GABAergic interneurons are also abundant in the MGD. Most MGD neurons respond over a wide range of latencies, typically longer than MG neurons, and exhibit broader frequency tuning, so a clear tonotopic organization is not obvious, if it is present at all.

The main ascending inputs to the MGD arise from the DCIC and LCIC (Malmierca 2003; Jones 2007) and may be either glutamatergic or GABAergic in nature (Bartlett and Smith 1999). The MGD projects to the nonprimary (belt) areas of auditory cortex.

The Medial Division of the Medial Geniculate Complex

The MGM is located medial to the MGv and MGD and stretches from the rostral to caudal poles of the MGB (Fig. 11). The MGM is rather heterogeneous with respect to cell types and connections. Several different types of cells have been identified including the magnocellular type, the largest neurons in the entire MGB (Fig. 12h–i; Winer and Morest 1983). Some of the neurons are calbindin reactive and project mainly to layers I and II of cortex. Projections to the middle layers of cortex arise from both calbindin- and parvalbumin-positive neurons (Jones 2007). Some neurons are narrowly tuned to frequency and respond robustly at short latencies, similar to MGv neurons, while others are broadly tuned and have longer latencies. Some authors define a separate division referred to as suprageniculate nucleus (Fig. 12j–k).

MGM receives inputs from both auditory and nonauditory sources. The main auditory inputs

arise from the cortical regions of the IC, as well as the CNC, SOC, and VLL (Anderson et al. 2006; Malmierca et al. 2002). Nonauditory inputs include the deep layers of the superior colliculus and other nuclei that appear to drive responses to somatic, vestibular, visual, and nociceptive stimuli in some species (see Jones 2007). In addition to auditory cortex, the MGM also projects to the striatum and amygdala (Doron and Ledoux 1999).

The Auditory Cortex

The auditory cortex (AC) is located in the temporal lobe of the cerebral hemisphere and represents the site of termination for fibers ascending from the auditory thalamus (Fig. 2). The most obvious species differences observed in the auditory brain are those seen in the AC (Fig. 13). For example, the number of areas identified in the AC ranges from 5 to 6 in mice and rats, 6–9 in cats and ferrets, 10–12 in primates, and over

Anatomy and Physiology of the Mammalian Auditory System, Fig. 13 Schematics of auditory cortex models in several mammals. Primary (core) auditory

areas are shaded. Tonotopic gradients are indicated by H (high) and L (low) frequency. (Reproduced from Malmierca and Hackett 2010)

30 in some studies of humans (Fig. 13). Species differences include the number of areas present, their relative position and arrangement, cell density, connections, and tonotopic organization, and it is likely that species differences will also be reflected in the organization of auditory cortex in other ways. However, a common theme is that a central primary region, or *core*, is surrounded by a variable number of secondary, or *belt*, areas in all mammals studied (Fig. 13). In nonhuman primates, the core–belt scheme has been extended to include a third region, known as the *parabelt* (Kaas and Hackett 1998; Winer and Schreiner 2011).

The Core Region of Auditory Cortex

The core region is made of the primary field (A1) and two other tonotopically organized areas (Fig. 13). Areas in the core are characterized by high cell density in a thick layer IV, dense myelination across laminae, and relatively high expression of several markers in the horizontal band involving layers III and IV, compared to secondary areas in the belt (Jones 2003; Kaas and Hackett 1998). Several different classes of pyramidal and nonpyramidal cells are found across the six layers of auditory cortex (Winer 1992). Pyramidal cells tend to be glutamatergic and are concentrated in layers III and V, while many nonpyramidal cells are GABAergic and account for about one-fourth of the neurons in most layers, except layer I, where they constitute more than 90%. Layer II contains both pyramidal and nonpyramidal neurons. The smaller cells are located superficially in layer II, while the larger pyramidal cells predominate near the border with layer III. Layer III is populated by several types of pyramidal and nonpyramidal cells. Layer IV is mainly populated by small tufted cells, which have radially oriented dendritic fields and are involved mainly in local columnar projections. Layer V contains both pyramidal and nonpyramidal neurons. The somata of the conspicuous large pyramidal neurons located in layer Vb have apical dendrites that extend to layer I, with several branches along the way. Other pyramidal

cells in layer V are smaller and more evenly distributed. Layer V is of particular interest because its cells form part of the projection to the thalamus and other subcortical areas (Fig. 14; Games and Winer 1988; Hefti and Smith 2000; Malmierca and Ryugo 2011). As in other cortical regions, two distinct types of pyramidal cells, “intrinsically bursting” and “regular spiking” can be distinguished on the basis of their correlated morphology and physiology (Fig. 14; Kawaguchi 1993; Kasper et al. 1994). The *intrinsically bursting* pyramidal cells (Fig. 14) have large cell bodies and long, thick apical dendrites that branch extensively in layer I. Their axons arborize locally in the infragranular cortical layers and project into subcortical white matter. In contrast, the *regular-spiking* pyramidal cells (Fig. 14) have smaller cell bodies and a thinner apical dendrite that seldom extend to layer I. Their axons also project to the white matter and arborize locally in the supragranular cortex. In slice preparations, the intrinsically bursting neurons exhibit a characteristic firing pattern with a burst of action potentials followed by either additional bursts or single spikes, whereas the regular spiking neurons tend to fire single spikes with a variable degree of adaptation (Hefti and Smith 2000, 2003). Intrinsically bursting cells make up the majority of layer V’s input to subcortical targets (Fig. 15; Games and Winer 1988; Winer 1992; Weedman and Ryugo 1996a, b; Saldaña et al. 1996) and are capable of providing a robust input to postsynaptic neurons (Hefti and Smith 2000). In contrast, most regular spiking neurons are strongly inhibited and may provide less robust but perhaps more specific, information to their inputs. Finally, layer VI has the widest variety of cell types, including several classes of pyramidal cells and multipolar, bipolar, and horizontal cells.

The main source of ascending inputs to A1 and other core areas is the MGv (Fig. 2; Jones 2007; Winer 1985; Winer and Lee 2007). The thalamocortical termination is concentrated in layers III and IV. The organization of these connections is topographic, reflecting tonotopic organization within the MGv, as well as the areas to which it projects. Additional inputs to the core

Anatomy and Physiology of the Mammalian Auditory System, Fig. 14 *Top panel*, examples of morphology of layer V and layer VI corticothalamic neurons biocytin-filled corticothalamic neurons. Scale bar 100 μ m; *Bottom panels*, Llano and Sherman model of differences of synaptic input and response properties between auditory layer V and layer VI corticothalamic neurons. In response to excitatory input, layer V corticothalamic neurons fire a burst of action potentials at low threshold, and these neurons receive excitatory input from neurons in layers II/III, IV, and V (gray) and GABA-mediated inhibitory input mostly from lower layer V with a smaller contribution from layer II/III (red). In contrast, in response to excitatory input, these neurons fire a regular train of individual action potentials, and these neurons receive excitatory input primarily from layer VI and inhibitory input from adjacent areas in layer VI (Figure kindly provided by Dr. Daniel Llano. Adapted from Llano and Sherman 2009)

include MGM, which projects broadly to all areas of auditory cortex. The intracortical connections of the core mainly include other areas of auditory cortex ipsilaterally and sparse connections with areas beyond auditory cortex. Tonotopically matched sites are more densely interconnected than non-matched sites (Lee and Winer 2005). Connections with auditory cortex in the opposite hemisphere are concentrated in the homotopic (matching) area, (Wallace and Harper 1997) and heterotopic connections are relatively weak. The main callosal projections arise from both pyramidal and nonpyramidal cells in layers III and V. Layers V and VI represent the main source of descending projections to the MGB and IC and brainstem (Fig. 15).

The Belt Region of Auditory Cortex

Areas that lie outside of the core region are often referred to as the nonlemniscal or belt areas (Fig. 13). These areas are anatomically and physiologically distinct from the core fields and from one another. Architectonically, each of the belt areas is distinct, but compared to the core region, cell density and myelination are generally reduced, as is the expression of cytochrome oxidase, acetylcholinesterase, and parvalbumin (Jones 2003).

In addition to the inputs from the core, the main source of projections to most of the belt areas is the MGD (Jones 2007; Winer 1985; Winer and Lee 2007). Additional connections include the MGM and thalamic nuclei that surround the MGB. Belt areas tend to differ with respect to the balance of inputs from different thalamic nuclei. In nonhuman primates, an additional group of areas has been identified that surround the belt areas adjacent to the core. This region is known as the *parabelt* (Kaas and Hackett 1998). The parabelt region receives inputs from the belt region and MGD, but not the core. Thus, some ascending information appears to pass serially through the core and belt regions before reaching the parabelt (Kaas and Hackett 1998).

The Descending Auditory Pathways

In parallel to the ascending auditory pathways, there are stepwise, descending projections from the auditory cortex to the organ of Corti (Fig. 15). The descending auditory pathway could be considered to consist of both (1) a descending chain

of connections and (2) a series of regional feedback loops (Warr 1992).

The descending chain comprises three main levels. The first level originates in the AC and includes corticothalamic, corticotectal, and corticopontine projections (Fig. 16). The corticothalamic projection forms reciprocal and

Anatomy and Physiology of the Mammalian Auditory System, Fig. 16 Diagrammatic summary of the laminar organization of cortical cells projecting to the inferior colliculus (IC), superior olivary complex (SOC), and cochlear nucleus (CN). All three distributions overlap;

however, the cortical neurons projecting to more distant targets are more narrowly distributed and centered in deeper regions of layer V (Figure kindly provided by Dr. D. K. Ryugo. Reproduced from Doucet et al. 2003)

nonreciprocal connections between the AC and MGB. The corticotectal projection terminates in the IC and subcollicular nuclei (Feliciano and Potashner 1995; Meltzer and Ryugo 2006). The second level of the chain originates in the IC, whose descending fibers form colliculo-olivary and colliculo-cochleoneuronal projections (Fig. 15). The colliculo-olivary fibers terminate on the periolivary medial olivocochlear cells which supply the OHCs (Caicedo and Herbert 1993; Faye-Lund 1985; Vetter et al. 1993). They may also terminate on lateral olivocochlear cells, which supply the IHCs (Feliciano and Potashner 1995). The last and third level of the chain consists of the olivocochlear system that provides

efferent innervation to the cochlea (Figs. 15 and 19).

The regional feedback loops consist of a series of cortical projections to subcortical nuclei that project back to cortex, directly or indirectly, allowing AC to control its inputs from lower centers.

The Corticofugal Pathways

The major AC projections target the MGB and IC (Figs. 15–18), but there are also AC projections to subcollicular nuclei, including the nucleus sagulum, paralemniscal regions, superior olivary complex, cochlear nuclear complex, and pontine

nuclei. The AC also supplies the amygdala, basal ganglia, striatum, superior colliculus, and central gray (reviewed in Malmierca and Ryugo 2011, 2012), suggesting that the AC has important roles in addition to auditory sensory processing (Winer 2006).

In the auditory thalamus, the MGV receives its heaviest source of input from the primary AC, while the MGM the least and the MGD receives an intermediate amount. A prominent feature of the corticothalamic projection is reciprocity, in which a cortical region projects to the part of the thalamus from which it receives input. However, there are also nonoverlapping regions (Llano and Sherman 2008). In the MGB, there are two main types of terminal synaptic boutons (I and II) arising from the core of the AC (Fig. 17; Bartlett et al. 2000; Llano and Sherman 2009). Type I terminals are small ($<1\ \mu\text{m}$ in long-axis diameter), synapse on small caliber dendrites of the MGV and MGD, and arise from the pyramidal cells of layer VI. Type II terminals are large ($>2\ \mu\text{m}$ in long-

axis diameter), mostly synapse in the MGD and occasionally in the MGM (Bartlett et al. 2000; Llano and Sherman 2009) and arise from pyramidal neurons from layer V.

Sherman and Guillery (1996) first proposed the notion of “drivers” and “modulators” of thalamic neurons in the visual and somatosensory thalamus, but this hypothesis has been applied to the auditory system as well (Llano and Sherman 2008). According to this theory, type I terminals play a modulatory role in the first-order thalamic nuclei, such as the MGV (Fig. 17). Thus, the corticothalamic inputs converge with ascending inputs on thalamic neurons such that the ascending inputs drive the thalamic neurons and the cortical inputs modulate them. In contrast, in the “higher-order” thalamic nuclei, such as the MGD, the “driver” inputs arise from the large type II axons and terminals that originate from the cortex and interact with other ascending input from the IC.

The corticofugal projection is glutamatergic and modulates the MGB responses to sound through a direct excitatory pathway, but the AC can also provide the MGB with an inhibitory influence (Bartlett et al. 2000) via its projections to the auditory sector of the thalamic reticular nucleus which, in turn, projects to the MGB.

As in the MGB, AC may modulate the processing of sounds in the IC through the activation of local inhibitory connections within the IC. Several studies have shown direct neocortical projections to regions surrounding the lateral lemniscus, including the nucleus sagulum ipsilaterally and the SOC and CNC bilaterally (Feliciano and Potashner 1995; Weedman et al. 1996; Weedman and Ryugo 1996a, b).

Anatomy and Physiology of the Mammalian Auditory System, Fig. 17 Diagram of a cortico-thalamocortical model of cortical processing. Information reaches the *lemniscal* AC via a projection from the MGV to layer IV of either the AAF or the AI. From here, a layer 5 pyramidal projects to the MGD, where a thalamocortical relay cell projects to layer IV of the *nonlemniscal* AC (DP or AII). From the nonlemniscal AC, a layer VI projection is sent to the MGB, adhering to the principle that all thalamocortical projections, whether coming from the first- or higher-order thalamus, receive a modulator, reciprocal projection from layer VI (Figure kindly provided by Dr. Daniel Llano. Adapted from Llano and Sherman 2008)

The Colliculofugal Pathways

Studies in several species have shown that the IC has descending projections to the LL, SOC, and CNC (Fig. 15; reviewed in Malmierca and Ryugo 2011, 2012). Perhaps, the most interesting projections are the *colliculo-olivary* projections that originate in the CNIC and LCIC because they terminate on the VNTB, the site of origin of the

Anatomy and Physiology of the Mammalian Auditory System, Fig. 18 Retrograde labeling in area Te1 for a rat that received an injection of Fast *blue* (FB) into the CNC and Diamidino *yellow* (DiY) into the IC (*top*). (a) Sagittal view of the brain, the *gray line* through AC indicates the position of the cells along the rostral/caudal axis display of the location of labeled cortical cells shown in panels (b–e). (b) Photomontage of layer V with few FB-labeled cells located in deep layer V whereas the DiY-labeled neurons are distributed more broadly. (c) Higher magnification photomontage illustrating the

laminar organization of cortical cells (cortical surface is towards the *top*) projecting to the CNC (*blue*) vs those targeting the IC (*yellow*) within layer V. (d and e) Examples of labeled cortical cells. Cortical cells that contained both dyes (*blue and yellow arrow* in d) were observed much less frequently (Figure kindly provided by Dr. D. K. Ryugo). Reproduced from Doucet et al. 2003). Abbreviations in the figure: CN Cochlear nucleus, CIC Central nucleus of the inferior colliculus, D Dorsal, M Medial, Te1 Temporal area 1, Te2 Temporal area 2, Te3 Temporal area 3

MOC (White and Warr 1983), suggesting that the IC influences MOC neurons (Vetter et al. 1993). The IC also projects to nonauditory nuclei including the pontine nuclei, lateral paragigantocellular nucleus, gigantocellular reticular nucleus, ventrolateral tegmental nucleus, and caudal pontine reticular nucleus (Caicedo and Herbert 1993).

The Olivocochlear System

The olivocochlear bundle provides the organ of Corti with efferent innervation (Figs. 15 and 19; Rasmussen 1946) and plays a critical role in maintaining the normal operation of the cochlea (Figs. 15 and 19). It may introduce nonlinear dynamics into the auditory system (Eggermont 2001). There are two systems of olivocochlear neurons, medial (MOC) and lateral (LOC). The MOC neurons are located medial and ventral to the main nuclei of the SOC in the PO nucleus known as the VNTB and project mainly to the

contralateral cochlea, whereas the LOC neurons are located within or near the LSO and project to the ipsilateral cochlea (Warr 1992; White and Warr 1983).

The MOC neurons constitute a homogeneous population of cholinergic cells and innervate the OHCs (Figs. 15 and 19). About 75% of them originate on the contralateral side with the remainder originating ipsilaterally (Warr 1992; Brown and Levine 2008). They probably receive descending input from the ipsilateral IC and ascending input bilaterally from the VCN.

In rodents, the LOC neurons (Figs. 15 and 19) consist of two distinct types of neurons: *intrinsic* and *shell* neurons (Vetter and Mugnaini 1992; Warr et al. 1997). *Intrinsic neurons* are confined to the ipsilateral LSO and constitute about 85% of all LOC neurons (Brown and Levine 2008; Vetter and Mugnaini 1992; Warr et al. 1997). Most *shell neurons* surround the ipsilateral LSO and constitute the remaining 15% (Vetter and Mugnaini 1992; Brown and Levine 2008; Warr et al.

Anatomy and Physiology of the Mammalian Auditory System, Fig. 19 Scheme of the LOC and MOC neurons, their projections to the IHCs and OHCs, respectively, and afferent fiber types I and II projecting to the

CNC. In rodents, two types of LOC cells occur: intrinsic located inside the LSO and shell located in the margins of the LSO (Figure kindly provided by Dr. Bruce Warr. Adapted from Warr 1992)

1997). (In contrast, in the cat the LOC neurons surround the LSO, and two populations have not been distinguished.) The LOC neurons innervate the type I primary afferent fibers near the region where they contact the IHCs. Virtually all of them originate on the ipsilateral side (Brown and Levine 2008).

The functional role of the MOC neurons may be to enhance transduction or signal detection through an unmasking effect, thus regulating the slow motility of the OHCs and thereby the stiffness of the basilar membrane (Eggermont 2001). Another function may be to protect the inner ear from acoustic injury (Taranda et al. 2009). Although the functional role of the LOC is uncertain, several studies (Safieddine et al. 1997; Safieddine and Eybalin 1992) have shown that these neurons may provide a modulatory effect to the afferent fibers that contact the IHCs.

Anesthesia, Neural Population Models of

D. Alistair Steyn-Ross¹, Moira Steyn-Ross¹ and Jamie Sleigh²

¹School of Engineering, University of Waikato, Hamilton, New Zealand

²Waikato Clinical School, University of Auckland, Waikato Hospital, Hamilton, New Zealand

Definition

General anesthesia is a reversible, drug-induced state of unconsciousness characterized by lack of awareness of surroundings, lack of responsiveness to painful stimuli (nociception), and inability to form memories (amnesia). The change in brain state from wakeful to unconscious produces alterations in cortical electrical activity that can be monitored with electrodes placed on the scalp (electroencephalogram (EEG)) or on the surface of the cortex (electrocorticogram (ECoG)). The goal of neural modelers is to develop equations that describe the gross behavior of spatially averaged populations of neurons during both induction of and recovery from general anesthesia.

Detailed Description

Classes of General Anesthesia

There are two broad classes of anesthetic drugs: inductive agents (such as propofol, etomidate, isoflurane) that produce a slowed sleeplike EEG and dissociative agents (e.g., ketamine, nitrous oxide) that induce a dissociated state with an activated EEG similar to that of REM sleep.

Most commonly used intravenous and volatile agents – such as propofol or sevoflurane – boost inhibition by increasing the influx of chloride ions at gamma-aminobutyric acid (GABA) receptors on postsynaptic membranes (Weir 2006), causing the postsynaptic neuron to become hyperpolarized. In contrast, dissociative drugs are believed to disrupt excitatory synaptic transmission. In both cases, the excitatory – inhibitory balance required for normal brain function has been shifted to favor inhibition.

The Induction: Recovery Trajectory

At low concentrations, most GABAergic agents (e.g., propofol, sevoflurane, etomidate) cause a paradoxical boost in cortical activity (called the “biphasic effect”) across most EEG frequency bands (Kuizenga et al. 2001), with the biphasic peak appearing first in the high beta frequencies (24–28 Hz), then sliding smoothly towards lower frequencies in time (e.g., see Fig. 3 of Koskinen et al. (2005)). With further increase in concentration, the EEG slows as large-amplitude delta-band oscillations (1–4 Hz) become dominant, then changes to an intermittent burst-suppression pattern (bursting activity alternating with relative silence), and finally collapses into a flat-line trace at the deepest levels of comatose anesthesia.

This sequence is reversed as the anesthetic drug is eliminated naturally from the body, allowing the patient to return to consciousness. However, the fact that the recovery of responsiveness generally occurs at a *lower* drug concentration (as measured in the blood) than that required to induce unresponsiveness suggests a hysteresis separation between induction and recovery trajectories. Part of this hysteresis can be explained in terms of the time required for the drug to diffuse

across the blood–brain barrier (Voss et al. 2007) and so can be compensated using pharmacokinetics models (Roberts 2007), but such compensations are typically only partially successful (Ludbrook et al. 1999; Coppens et al. 2010). The remaining hysteresis may be a consequence of a recently proposed “neural inertia” that resists transitions between conscious and unconscious states (Friedman et al. 2010); such distinct induction/recovery paths arise naturally if the brain has access to multiple steady states as suggested by the modeling of Steyn-Ross et al. (1999, 2004).

Cellular Effects of General Anesthetic Drugs

Studies of propofol, halothane, and isoflurane have shown that, at drug concentrations rendering human subjects unresponsive, cerebral blood flow and metabolism are reduced by about 50% (Antkowiak 2002) as a result of global reductions in cortical activity. This is consistent both with in vivo investigations in rat cortex – where sedative-level concentrations were found to suppress neural firing rates by 50–70% (Gaese and Ostwald 2001) – and with cultured brain-slice studies in which low concentrations of general anesthetics (GABAergic agonists propofol, halothane, isoflurane, enflurane, sevoflurane, etomidate, ethanol, and pentobarbital and the non-GABAergic agent ketamine) significantly decreased mean firing rates (Antkowiak 2002).

All anesthetic drugs influence cellular function in a number of different ways, but the major mechanism for GABAergic suppression of firing rates is believed to be the prolongation of the opening of chloride channels on the postsynaptic neuron, thus causing a substantial increase in negative charge transfer (by a factor of 2–4 times control at clinically relevant concentrations (Kitamura et al. 2003; Banks and Pearce 1999)) during the inhibitory postsynaptic current (IPSC) pulse.

Dissociative drugs reduce excitatory transmission by blocking *N*-methyl-d-aspartate (NMDA) glutamate channels, which probably has a significant role in producing the characteristic dissociated anesthetic state (Petrenko et al. 2013); however, these drugs also have other effects such as inhibition of hyperpolarization-activated

cyclic nucleotide-gated (HCN1) channels (Chen et al. 2009) or increased potassium channel opening (Gruss et al. 2004).

Modeling Anesthetic Effects

The challenge for anesthesia modelers is to bridge the scales from the microscopic cellular drug effects to the consequent *macroscopic* population behaviors detected with scalp or cortical electrodes. By considering spatially averaged (“mean-field”) properties of cortical tissue, we can avoid the need (and computational expense) of attempting to explicitly represent myriads of individual neurons (as is done in neural networks). There is a steadily growing interest in applying mean-field methods to the challenge of understanding anesthesia; see Foster et al. (2008) and Steyn-Ross et al. (2011) for reviews.

The notion of *neural fields* dates from foundation work by Wilson and Cowan (1972) that modeled the brain as homogenous populations of excitatory and inhibitory neurons. The first attempt at modeling propofol anesthesia by Steyn-Ross et al. (1999) incorporated prolongation of inhibitory response into the mean-field neural model of Liley et al. (1999); it predicted the possibility of multiple steady states with distinct first-order phase transitions between activated (“conscious”) and inactivated (“unconscious”) states and provided a possible explanation for the hysteretically separated biphasic power surges observed at loss and recovery of consciousness (Kuizenga et al. 2001).

Subsequent work by Bojak and Liley (2005) on isoflurane anesthesia showed that, for suitable choices of cortical parameters, a smooth descent into unconsciousness can also generate a biphasic drug response. Using an alternative mean-field model, Hutt and colleagues (Hutt and Schimansky-Geier 2008; Hutt and Longtin 2010) predicted that biphasic power surges can be expected for both the bistable (jump transition) and monostable (smooth) inductions of anesthesia.

General anesthetic agents are widely used to treat seizures, but paradoxically, some anesthetics (e.g., enflurane) can also provoke cortical seizures when the patient is deeply anesthetized. Liley and

Bojak (2005) and Wilson et al. (2006) used mean-field modeling to show that subtle changes in the shape and duration of the drug-induced inhibitory postsynaptic response can explain why enflurane, but not isoflurane, is seizurogenic.

An important part of general anesthesia is the suppression of noxious stimuli. A practical index of antinociception has been developed from a mean-field model (Liley et al. 2010) that informed construction of an autoregressive – moving-average (ARMA) noise-driven filter whose output approximates the scalp-recorded EEG. The mean filter frequency tracks the level of propofol-induced hypnosis (“cortical state”), while the decrease in required noise intensity (“cortical input”) tracks the concentration of a coadministered analgesic agent (remifentanyl). This computed “cortical input” signal is presumed to be a measure of cortical stimulus, both noxious and normal, entering from the thalamus, and potentially allows differentiation between hypnotic and analgesic drug effects.

The unconscious state of anesthesia and of deepest natural sleep are both characterized by large-amplitude, slow (0.5–4 Hz) delta waves of EEG activity. The source of these slow waves is unknown but is generally supposed to originate from gradual alternations in depolarizing and hyperpolarizing ionic currents. By introducing a slow ionic gating variable into a mean-field model for desflurane anesthesia, Molaee-Ardekani et al. (2007) demonstrated emergence of realistic slow waves. A quite different slow-wave mechanism has been proposed by Steyn-Ross et al. (2013): if inhibitory gap junctions are included in the two-dimensional cortical sheet, then a Turing (pattern-forming) instability can interact with a weakly damped low-frequency Hopf instability to produce turbulent slow-wave activity across the cortex. Anesthetic-induced closure of inhibitory gap junctions (Wentlandt et al. 2006) is predicted to weaken the Turing instability in favor of the Hopf oscillation.

There has been interest in modeling some of the specific details of EEG spectral changes caused by various general anesthetic drugs, for example, the displacement in alpha peak frequency induced by ketamine (Bojak et al. 2013)

or propofol (Hindriks and van Putten 2012; Hutt 2013) and the burst-suppression pattern of deep anesthesia (Liley and Walsh 2013).

Increasingly there has been a realization that general anesthesia may disrupt neuronal networks in an anatomically specific fashion (Kuhlmann et al. 2013; Lee et al. 2013) and that the current homogenous and isotropic neuronal population models might need to include aspects of network topology. This has led to attempts to link EEG patterns probabilistically with underlying anesthetic effects on inhibitory and excitatory neuronal groups – this should provide a quantitative basis for the estimation of model parameters. At an abstract level, dynamic causal-modeling methods have been employed (Moran et al. 2011; Boly et al. 2012), but a more direct Bayesian approach – which has been used for natural sleep (Dadok et al. 2013) – could be applied to anesthesia EEG.

Anti-Hebbian Learning

Yoonsuck Choe

Department of Computer Science and Engineering, Texas A&M University, College Station, TX, USA

Definition

Anti-Hebbian learning is a form of activity-dependent synaptic plasticity that is defined as the opposite of Hebbian learning. Hebbian learning is commonly defined as follows: correlated activation in the pre- and postsynaptic neurons leading to the strengthening of the connection between the two neurons. However, the original definition offered in Hebb (1949) talks about the increase in the presynaptic neuron's efficiency of eliciting activity in the postsynaptic neuron, under the same correlated firing condition. These two definitions (strengthening of connection vs. increased efficiency) are compatible only when the presynaptic neuron is excitatory. They are contradictory when the presynaptic neuron is inhibitory: increased connection strength (weight, efficacy) corresponds to decreased efficiency in

eliciting response. Assuming the original definition of Hebbian learning, we can define anti-Hebbian learning as a form of synaptic plasticity where correlated activation in the pre- and post-synaptic neurons leads to the reduction in the efficiency of the presynaptic neuron's ability to elicit activation of the postsynaptic neuron.

Detailed Description

In this entry, we will review computational formulations of anti-Hebbian learning and their theoretical implications. We will also briefly touch upon neurobiological correlates of the learning mechanism. The literature on anti-Hebbian learning is not as rich as that on Hebbian learning. A review of Hebbian learning by Frégnac (2003) includes a brief discussion on the neurobiological bases of anti-Hebbian learning. See Földiák (1990) for a computational treatment of the subject and Palmieri et al. (1993) for a review.

Basic Formulation

Consider a simple configuration with a single presynaptic neuron x connecting to a single post-synaptic neuron y with synaptic weight w as shown above (Fig. 1). Anti-Hebbian learning is the same as Hebbian learning, except for the flip of the sign.

$$\frac{dw}{dt} = -\eta xy, \quad (1)$$

where the learning rate η is a small, fixed, positive value. The neuronal activities x and y are normally assumed to be positive (or zero), but for purely computational purposes, they can be negative values as well. In Hebbian learning, adaptive threshold or normalization approaches are used

Anti-Hebbian Learning, Fig. 1 A pair of neurons forming an anti-Hebbian connection

to check unbounded growth in the synaptic weight. However, in anti-Hebbian learning, such a check is unnecessary since the mechanism is inherently stable (Földiák 1990). At first glance, it appears that the weight w can tend toward $-\infty$, but this will never happen because high levels of inhibition will shut off y after a certain point and thus w will not change any further thereafter. When x and y are allowed to be negative, w can increase under the same learning rule. Some formulations prevent this from causing infinite growth by imposing a limit (w is assumed to be negative and it is reset to 0 as soon as it becomes positive; Földiák 1990), but others do not include such a limit (e.g., Girolami and Fyfe 1996).

Theoretical Perspectives

Anti-Hebbian learning is usually combined with Hebbian learning to produce interesting theoretical and practical results. Figure 2 below shows such an example (adapted from Földiák 1990). In this figure, two downstream neurons y_1 and y_2 receive afferent input from x_1 and x_2 through Hebbian synapses (with weights v_{ij}) and exchange activations via anti-Hebbian lateral connections (with weights w_{ij}). (The subscripts ij on the weights indicate the target $[i]$ and source neuron index $[j]$, respectively.)

Földiák showed that the above network can learn to decorrelate the output neurons' activity (sparse coding in neurons y_i), which results in the learning of afferent representations (v_{ij}) that are components that make up the input mixtures. The model included an anti-Hebbian rule similar to Eq. 1 with an added threshold (w_{ij}), a Hebbian

Anti-Hebbian Learning, Fig. 2 Neurons connected with Hebbian (arrows) and anti-Hebbian synapses (discs). (Simplified from Földiák 1990)

Anti-Hebbian Learning, Fig. 3 A hierarchy of neurons y_i with Hebbian afferent connections (arrows) and anti-Hebbian connections in a cascade (discs). (Adapted from Carlson 1990)

rule with weight decay (v_{ij}), and a dynamic neural activation equation ($\frac{dy_i}{dt}$) with adaptive threshold and sigmoid nonlinearity (for details, see Földiák 1990).

Now consider a hierarchical network shown above (Fig. 3). Hebbian learning is known to extract the first principal component of the inputs (Oja 1982), so neuron y_1 would serve this role. Using a hierarchical network like Fig. 3 with anti-Hebbian connections arranged in a cascade, second, third, and subsequent principal components of the input can be found (see Carlson 1990 for a review and details). The main idea is that once y_i learned the i -th principal component, and y_{i+1} is decorrelated with $y_1, y_2, \dots, y_i$ through anti-Hebbian connections (note that y_3 receives anti-Hebbian connections from both y_1 and y_2), y_{i+1} will find the $i + 1$ -th principal component.

For a review of more complicated network topologies that involve anti-Hebbian learning, see Palmieri et al. (1993).

Neurobiological Underpinnings

As Hebbian learning is usually associated with long-term potentiation (LTP), anti-Hebbian learning is typically explained by long-term depression (LTD). LTP is a phenomenon where high frequency stimulation of the presynaptic neuron leads to a prolonged increase in synaptic efficacy (Bliss and Collingridge 1993). LTD is the

opposite, where low-frequency stimulation causes a prolonged decrease in synaptic efficacy (Dudek and Bear 1992); thus, it fits the anti-Hebbian profile.

Examples of LTD associated with anti-Hebbian mechanisms have been found in the mammalian cerebellum (e.g., mouse and rat) and also in the electrosensory lobe (ELL) in the teleost electric fishes, and these LTD mechanisms are thought to be playing an anti-Hebbian role (see Frégnac 2003 for a brief review).

In some cases, LTP can also be associated with a form of anti-Hebbian learning, when LTP is induced not by correlated activation but by pre-synaptic firing not being met by or negated by the postsynaptic activity. Such a phenomenon has been observed in the hippocampus and has been dubbed anti-Hebbian LTP. Kullmann and Lamsa (2007) provide an extensive review on this topic and provide a comparison of anti-Hebbian LTD and anti-Hebbian LTP.

Finally, spike timing-dependent plasticity (STDP; see Caporale and Dan 2008 for a review) has also been linked to anti-Hebbian learning. STDP is a short-term synaptic plasticity mechanism where depending on the ordering of pre- and postsynaptic events, either LTP or LTD can entail. LTP is induced when the presynaptic activity precedes postsynaptic activity and LTD when the ordering is reversed. Some views the LTD part of STDP as implementing an anti-Hebbian rule (see Nelson 2004 for a discussion).

Applications of Anti-Hebbian Learning

Anti-Hebbian learning has been applied to several signal and data processing tasks including vision and speech processing. Girolami and Fyfe (1996) used anti-Hebbian rule to learn finite impulse response (FIR) filter coefficients and applied the technique to blind source separation in the speech recognition domain. Schraudolph and Sejnowski (1992) used anti-Hebbian rule to learn invariances in disparity tuning for stereo vision. Földiák (1990) combined Hebbian and anti-Hebbian rule to learn sparse representations from overlapping visual inputs.

Application of Declarative Programming in Neurobiology

Thomas J. Anastasio

Department of Molecular and Integrative Physiology, and Beckman Institute, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Definition

The main technique in computational neuroscience is imperative programming, which is often used to implement simulations of dynamics, and describes *how* a computation is performed. A complement to this approach is declarative programming. Declarations provide descriptions of relationships between elements, effectively describing *what* the computation should accomplish. The use of declarative programming for modeling biological processes is still in its infancy (Fisher and Henzinger 2007) yet has shown itself to be a valuable first step for analysis of the seemingly impenetrable complexity of molecular interactomics: the interplay of the myriad proteins and signaling species in the cell. Declarative programming can also be used at the connectomic level of understanding connections among neurons or among brain areas.

Detailed Description

Declarative Programming

The *declarations* of a declarative program describe the relationships between system elements. Because of this descriptive nature, a model implemented in a declarative program may be considered as a system *specification*. Many declarative programming languages utilize term-rewriting logic: the declarations are rewrite laws that specify how one term should be replaced by another. Abstract rewriting systems are written with arrows, specifying that the left-hand side (LHS) is to be replaced by the term

on the right-hand side (RHS). Other notations, such as Backus-Naur Form, utilize some variant of an equal sign to specify that RHS is replaced by LHS.

Crucially, because the declarations are descriptions of system properties, the specification can be used not only for simulation but also for analyses such as state-space search and temporal-logic model checking (explained below; for a general reference see Huth and Ryan 2004). Term-rewriting declarative languages are readily used for expressing data-driven models constructed directly from experimental observations. These models do not require an overarching conceptual framework or preconceived hypothesis, allowing the enormous amounts of data generated by neurobiological experiments to be directly entered. This allows the data to “speak for itself” and provides a model that can be used as a tool to help develop subsequent hypotheses.

The first term-rewriting language was the λ -calculus, developed in the 1930s by Alonzo Church (Cardone and Hindley 2006). Since then several other term-rewriting, declarative programming languages have been developed. Some well-known examples are Scheme (<http://www.r6rs.org/>), Alloy (<http://alloy.mit.edu/alloy/index.html>), Simile (<http://www.simulistics.com/tour/declarative.htm>), and ECLiPSe (<http://eclipseclp.org/index.html>). One declarative programming language that has been used effectively for modeling molecular interactions and neurobiological processes is Maude (<http://maude.cs.uiuc.edu/>; Clavel et al. 2007).

A specification in Maude is based on an underlying algebra, which is defined by *sorts* (data types) and by *operations* that are allowed for each sort (e.g., natural numbers – sort, can be added together – operation). Preset algebras such as the natural numbers are available, but new algebras can be defined by the user. Declarations in Maude are written in terms of the underlying algebra and can be expressed either as equations or as rules. Equations in Maude specify functional relationships that simplify the state of the system being modeled, while rules specify transitional relationships that change the state of the model

system. For example, an equation could specify that 2 apples plus 4 apples plus 3 apples equals 9 apples, while a rule could specify that 9 apples can transition to an apple pie. Equations and rules can be unconditional (`eq` and `rl`, respectively) or conditional (`ceq` and `cr1`). For example, a conditional rule could specify that 9 apples can transition to an apple pie, but only if mom is available to bake it. While an unconditional equation or rule applies whenever its LHS is present, a conditional rule requires both the LHS and the required conditions.

All rewrite systems have rules (a.k.a. syntax) that transition the system state and evaluations (a.k.a. semantics) that can reduce the state, in whole or in part, to its underlying value at arbitrary times (Kain 1972). Another characteristic of Maude is that equations (i.e., evaluations) *must* execute whenever they apply while applicable rules may execute or not. Rules, by executing, can transition the system to a state in which equations become applicable that were not so in the previous state. In using Maude for simulation, all applicable rules would ultimately execute according to a *fairness criterion*: every applicable rule must execute once before any other rule can execute twice. In using Maude for analyses, such as state-space search or logical model checking, the rules execute in all possible combinations and orders. Because rules cause state transitions, Maude thereby elaborates the state transition tree implied by the specification and later searches this tree for specific states or to verify certain temporal-logic propositions.

Maude has been used to specify and analyze a broad range of complex engineered systems used for computer network security, encryption, and avionics, among others (Meseguer 2012). Maude is also used to model other programming languages, and analysis of a Maude model can verify that a language behaves as intended. This type of analytical capability suggests how Maude can be used to assess interactomic “programs,” so as to determine where they have vulnerabilities, predicting sites for potential failure which would produce disease, as well as sites where intervention could compensate for these failures,

predicting sites where pharmacological intervention would be of value.

Declarative Models of Neurobiological and Neurodegenerative Processes

Maude has been used to model several biological processes (Eker et al. 2002; Talcott 2008). An initial neurobiological application explores the synaptic plasticity thought to underlie fear conditioning and its extinction (Anastasio 2013b). In that microconnectomic model, rules specified synaptic weight changes while equations specified changes in neural responses caused by weight changes. Thus, each state of the model system had a different one of the many possible configurations of synaptic weights. This particular model had only nine synapses, which were allowed only a limited number of discrete weights, so the state space was large but still small enough to permit exhaustive search. Analysis via state-space search provided testable hypotheses by revealing which of these very many synaptic weight configurations were compatible with fear conditioning followed by extinction.

More recent neurobiological applications involve the food-intake control system (Tabebordbar and Anastasio 2016) and the monoaminergic neurotransmitter system (Camacho and Anastasio 2017). The system of hypothalamic neurons, distinguishable both in terms of sub-nucleus and neurotransmitter/neurohormone profile, was specified in Maude. State-space analysis revealed activation configurations consistent with new experimental findings that contradicted current understandings. For example, high food-intake had been associated only with high levels of activity of arcuate nucleus neurons secreting Agouti-related peptide (AgRP neurons). Search of the model state-space found many configurations consistent with that relationship but also found some configurations consistent with new findings that *low* AgRP neuron activity also can be associated with high food intake. The model showed how overall activity patterns, comprising all of the neurons modeled, which were consistent with high food-intake differed between those having low versus high AgRP neuron activity. The differences stand as

model predictions. A similar approach based on a model of the monoaminergic neurotransmitter system was used to study neuroadaptation to chronic antidepressant administration due to changes that are known to occur in various neurotransmitter/neurohormone receptor types. State-space analysis found many configurations adapted to chronic selective serotonin reuptake inhibitors (SSRIs) that nevertheless did not have serotonin levels that had been elevated to therapeutic levels. These findings provide an explanation for the low clinical efficacy of SSRIs, since elevated serotonin is thought to be the therapeutic mechanism of SSRIs. The analysis also uncovered chronic antidepressant combinations that should be more effective than single SSRIs in treating depression.

Maude models of some of the molecular interactions that underlie Alzheimer Disease (AD) have also appeared (Anastasio 2011, 2013a, 2014a, b, 2015). These studies were based on the amyloid hypothesis, which posits that AD results from buildup of the amyloid-beta peptide (Hardy and Selkoe 2002). A subset of the molecular and cellular interactions believed to underlie the regulation of amyloid-beta is diagrammed in Fig. 1.

Space constraints prohibit description of all of these interactions. They are based directly on findings from the primary literature and described in detail in Anastasio (2011). Each of 36 declarations specified how the level of biological activity of one model element, representing a molecular species, was determined through interaction among the others. Many model elements could assume multiple levels, so the entire state space was too large to be managed on a desktop computer. As an alternative to high-performance computing, the declarations, first specified as equations, were then divided into subsets that could be converted to rules. In this way, the space of configurations involving a subset of interactions could be analyzed using state-space search and temporal logical, while the rest of the interactions took place in the background.

An example of an equation in the Maude model of amyloid-beta regulation is

Application of Declarative Programming in Neurobiology, Fig. 1 Schematic diagram of many of the cellular and molecular interactions that regulate the level of the peptide amyloid-beta

```
ceq [PPARexpress] : PPARgene(G) NSAID
(X) cytokine(Y) PPAR(Z) =
PPARgene(G) NSAID(X) cytokine(Y) PPAR
(max(0, G + (X - Y)) * G)
if Z /= max(0, G + (X - Y)) * G.
```

This equation, labeled `PPARexpress`, describes the interaction that determines the level of the peroxisome proliferator-activated receptor (PPAR). The operator `PPAR(Z)` assigns integer level `Z` to PPAR, and the equation describes how that level is determined by the presence of its gene `PPARgene` and the levels of cytokines and nonsteroidal anti-inflammatory drugs (NSAIDs). This equation is conditional (`ceq`) and executes only if doing so changes the level assigned by PPAR. To convert this conditional equation to a conditional rule, it would be relabeled `cr1` and `=` would be replaced with `=>`.

The model depicted in Fig. 1 incorporates the hypothesis that mild cerebrovascular disease (CVD) can trigger amyloid-beta accumulation (Scheibel et al. 1989; de la Torre 2009). Simulations and analysis were focused on compounds known to modulate the activities of model elements. Specifically, cilnidipine blocks hypoxia-inducible factor (HIF) (Oda et al. 2009) while ifenprodil blocks caspase 3 (`casp3`) (Dave et al. 2003). It was of interest to see whether a HIF-blocker or a `casp3`-blocker would be more effective in reducing the rise of amyloid-beta in the presence of CVD in the model.

In the model, amyloid-beta rose from its normative level of 4 to the pathological level of 8 in the presence of CVD (Table 1). NSAIDs, known to increase PPAR levels in vitro (Sastre et al. 2006), and HIF-blocker each separately held the rise of amyloid-beta to 5 while `casp3`-blocker only held it to 7. NSAID and HIF-blocker together held amyloid-beta to its normative level of 4 but `casp3`-blocker provided no further benefit in combination with NSAID or HIF-blocker or both.

These simulations showed that an HIF-blocker was more effective than a `casp3`-blocker in reducing the rise of amyloid-beta in the face of CVD. We then used temporal-logic analysis to show why this effect occurs. Temporal-logic analysis

Application of Declarative Programming in Neurobiology, Table 1 Modeling the effects of nonsteroidal anti-inflammatory drugs (NSAIDs) and blockers of hypoxia-inducible factor and caspase 3 (HIF-blocker and `casp`-blocker) on the level of amyloid-beta in the presence of incipient cerebrovascular disease (CVD)

CVD	NSAID	HIF-blocker	Casp-blocker	Amyloid-beta
0	0	0	0	4
1	0	0	0	8
1	1	0	0	5
1	0	1	0	5
1	0	0	1	7
1	1	1	0	4
1	1	0	1	5
1	0	1	1	5
1	1	1	1	4

provides answers to questions such as whether a particular property is always true, never true, or only true after some other property becomes true. For the AD model, temporal-logic analysis was used to determine the value of propositions of the form $\sim \text{hasAPO} \text{ U } \text{cytACT}$, where `hasAPO` is the property that apoptosis has occurred, `cytACT` is the property that cytokines have been activated, and $\sim$ and `U` are the temporal-logic operators “not” and “until,” respectively. Maude demonstrated that this proposition is true, meaning that apoptosis will not occur until cytokines are activated in the model. That is important because apoptosis activated caspase 3 in the model. Similar analyses revealed that cytokines were not activated if HIF-blocker was present. Taken together, the temporal-logic analyses show that `casp3`-blocker was not effective in combination with HIF-blocker because HIF-blocker already prevented caspase 3 activation.

These analyses made several testable predictions:

1. An HIF-blocker will be effective in reducing amyloid-beta levels in the presence of incipient CVD.
2. A `casp`-blocker will be less effective than an HIF-blocker.

3. A casp-blocker will provide no further benefit if administered in conjunction with an HIF-blocker.
4. NSAIDs will be more effective in combination with an HIF-blocker than alone.

Conclusion

Declarative programming can be applied in the simulation and temporal-logic analysis of complex neurobiological processes, whether normal or pathological. The phenomenon at issue in the above example, the regulation of amyloid-beta, occurs predominantly on the molecular level. However, term-rewriting and declarative programming can also be used to create and analyze models of neurobiological phenomena at all scales, from molecular to cellular to network to whole brain, or to create multiscale models in order to understand phenomena arising from interactions across multiple scales.

Definition

Information theory is a practical and theoretical framework developed for the study of communication over noisy channels. Its probabilistic basis and capacity to relate statistical structure to function make it ideally suited for studying information flow in the nervous system. It has a number of useful properties: it is a general measure sensitive to any relationship, not only linear effects; it has meaningful units which in many cases allow direct comparison between different experiments; and it can be used to study how much information can be gained by observing neural responses in single trials, rather than in averages over multiple trials. A variety of information-theoretic quantities are commonly used in neuroscience – (see entry ► [“Summary of Information-Theoretic Quantities”](#)). In this entry we review some applications of information theory in neuroscience to study encoding of information in both single neurons and neuronal populations.

Detailed Description

Information Analysis of Spike Trains to Investigate the Role of Spike Times in Sensory Coding

Mutual information is a widely used tool to study how spike trains encode sensory variables.

A typical application of mutual information to spike train analysis is to use it to compare the information content of different representations of neural responses that can be extracted from spike trains. The neural code used by a neuron is often defined operationally as the smallest set of response variables that carries all (or almost all) the information contained in the spike train of the neuron. Mutual information is used to quantify the information content of increasingly complex representations of the neural response, and the simplest representation that carries the most information is chosen as the putative neural code.

An example of this general approach is the investigation of the role of spike times in encoding information. The most established hypothesis on how sensory information is represented in the brain is the spike count-coding hypothesis (Adrian 1928) which suggests that neurons represent information by the number of spikes discharged over some relevant time window. Another hypothesis is the spike timing encoding hypothesis, which suggests that the timing of spikes may add important information to that already carried by spike counts (Rieke et al. 1997; Panzeri et al. 2001). Information theory can be used to understand the role of spike times in carrying sensory information, by using it to characterize the temporal resolution needed to read out the information carried by spike trains. This can be performed by sampling the spike train at different temporal precisions, Δt , (Fig. 1a) and computing the information parametrically as a function of Δt (Ruyter et al. 1997). The temporal precision required to read the temporal code then can be defined as the largest Δt that still provides the full information obtained at higher resolutions. If this precision is equal to the overall length of the window over which neurons carry information, then information is carried only by the number of spikes. As an example, we carried out this type of analysis on the responses of neurons from the VPM thalamic nucleus of rats whose whiskers were stimulated by fast white noise deflections (Montemurro et al. 2007). We found that the temporal precision Δt at which neurons transmitted information about whisker deflections was finer than 1 ms (Fig. 1b), suggesting that these neurons

Applications of Information Theory to Analysis of Neural Data, Fig. 1 *Effect of temporal resolution of spike times on information. (a)* The response of a neuron is initially recorded as a series of spike times. To investigate the temporal resolution at which spike times carry information, the spike train is binned at a variety of different time resolutions, by labeling the response at each time with the number of spikes occurring within that bin, thereby transforming the response into a discrete integer

sequence. **(b)** The information rate (information per unit time) about whisker deflections carried by VPM thalamic neurons as a function of bin width, Δt , used to bin neural responses. Information rate increased with bin resolution up to 0.5 ms, the limit of the experimental setup. This shows that a very fine temporal resolution is needed to read out the sensory messages carried by these thalamic spike trains. (Figure reprinted with permission from Ince et al. 2010)

use high-precision spike timing to carry information.

Information Analysis of Local Field Potentials to Examine the Information Content of Network Oscillations

Information analysis in neuroscience is not limited only to spike train analysis, but it has been used also to study the measure of massed population activity, such as local field potentials (LFPs) (Buzsáki et al. 2012). LFPs are operationally defined as the low-pass filtered extracellular potential measured by an extracellular intracranial electrode. There are at least three reasons why LFPs are widely used in neuroscience. The first is that they are more easily and stably recorded in chronic settings than is the spiking activity of individual neurons. The second is that the LFP captures key integrative synaptic processes and aspects of subthreshold neural activity that cannot be measured by observing the spiking activity of a few neurons alone (Einevoll et al. 2013). The third is that LFPs are more sensitive to network oscillations than measures of spiking activity from small populations. LFPs from a sensory area typically show a power spectrum containing

fluctuations over a wide range of frequencies, from <1 to 100 Hz or so. Given that the power of oscillatory activity typically increases during the presentation of a sensory stimulus, many authors have speculated that this oscillatory activity plays a role in brain communication and in particular in sensory-related computations. However, understanding the function of these oscillations has remained elusive and controversial. To gain insights into the function of oscillations in sensory encoding, it is important to understand how they contribute to the representation of the natural sensory environment.

This problem can be addressed by quantifying the oscillation power in any given trial in response to different stimuli and then computing the information gained by the power at each frequency. Since the power is a continuous variable, the computation of its information is potentially more difficult than the one based on discrete variables like the spike train ones described above. There are at least two ways to solve this problem. The first is to discretize the power in a number of equi-populated bins and to use bias corrections to eliminate the bias. The second is to fit the data to a parametric distribution. In this case, it is worth

reminding that the power computed with most spectral methods follows a chi-square distribution, and thus, its square or third can reasonably be well approximated by a Gaussian distribution (Magri et al. 2009). This makes the computation of information relatively straightforward. The third potential approach is to use binless methods such as Nearest Neighbors approaches (Kraskov et al. 2004). We tried out these methods extensively on computation of information in power of LFPs, obtaining very similar results with all approaches (see, e.g., Magri et al. 2009).

We applied this method to recordings from primary visual cortex of anesthetized macaques during stimulation with naturalistic color movies (Belitski et al. 2008; Magri et al. 2012a). This revealed, for the first time, how information about the naturalistic sensory environment is spread over the wide range of frequencies expressed by cortical activity. Although the broadband nature of the spectrum suggests a contribution to coding from many frequency regions, we found that only two separate frequency regions contribute to coding: the low-frequency range and the gamma range (Belitski et al. 2008; see Fig. 2 below). Interestingly, low- and high-frequency ranges act as perfectly complementary or “orthogonal” information channels: they share neither signal (i.e., stimulus information) nor “noise” (i.e., trial to trial variability for a fixed stimulus). This finding has several implications. First, it shows that, despite the broadband spectrum,

only a small number of privileged frequency scales are involved in stimulus coding. Second, it suggests that high-frequency and low-frequency oscillations are generated by different stimulus-processing neural pathways. Third, the finding that different frequency bands code different sensory features in separate, truly independent information channels reinforces the concept of “cortical multiplexing” that we proposed above.

Information Analysis of Imaging Data to Study Neural Population Coding or Coupling Between Different Neural Signals

The analysis tools that we have described above have, to date, largely been applied to spike train and time series data recorded using electrophysiological techniques. However, in recent years, imaging technologies have been developed which are capable of resolving neural signaling at systems’ cellular and subcellular resolutions on a single trial basis (Denk et al. 1990, 1994; Stosiek et al. 2003; Chen et al. 2013). One way to apply information-theoretic tools to the analysis of such imaging data is to convert the data to a “spike train,” for instance, by applying an algorithm for the detection of action potential-evoked calcium transients to calcium imaging data (Oñativia et al. 2013). Such an approach has been used to perform information-theoretic analysis of simultaneously recorded populations of cerebellar Purkinje cell complex spikes extracted from in vivo calcium imaging movies (Schultz et al. 2009). However,

Applications of Information Theory to Analysis of Neural Data, Fig. 2 The visual information carried by LFP power at different frequencies. (a) LFP power spectrum of V1 recordings anesthetized macaques either during spontaneous activity in the dark (dashed line) or during the

presentation of a color movie stimulus (solid line). (b) Information about the movie stimulus carried by LFP power at different frequencies. The area indicates the SEM. (Reproduced from Magri et al. 2012a)

the use of imaging data may also allow a wider set of questions to be approached than can be examined electrophysiologically, by directly examining patterns of pixel intensities.

Another interesting application of information theory to neuroimaging data regards its use for understanding the nature of the coupling between neural activity and fMRI responses. In fact, although there is evidence that fMRI BOLD responses reflect neural activity, it is not clear whether the BOLD signal reflects only the total power of massed neural activity, or only the power in a given band, or rather the relationships between powers of neural activity in different frequency bands. This problem can be cast theoretically into quantifying whether more information about BOLD can be gained from simultaneously observing the power of neural activity in two or more bands of neural activity than the information gained by observing either band alone. Because mutual information captures all the ways a signal may statistically relate to another, finding that another signal carries extra information demonstrates that this signal truly provides some information that cannot be possibly obtained from the first one. This does not necessarily hold when using methods that capture only specific relationships between signals. For example, an increase in predictability based on linear models may reflect both additional information from the second regressor as well as information that was already present in the first regressor but was not captured by the linear assumption. Application of this idea to simultaneous recording of LFPs and fMRI BOLD in primary visual cortex showed that the beta and alpha bands carry information about BOLD that complements that carried by the gamma band, the band that most correlates to the BOLD signal (Magri et al. 2012b).

Since imaging signals such as fMRI have an analogue rather than discrete nature, the practicality of application of information theory to analogue brain signals is crucially dependent upon the development of appropriate regularization and dimensionality reduction algorithms. These might stem from simple yet efficient discretization algorithms (Belitski et al. 2008; Magri et al. 2009),

Nearest Neighbors regularization algorithms (Kraskov et al. 2004), the use of manifold learning techniques for nonlinear dimensionality reduction (Roweis and Saul 2000; Seung and Lee 2000; Gan 2006), and/or the evaluation of information through a decoding step (Quiñero Quiroga and Panzeri 2009).

Associations and Rewards in the Auditory Cortex

Michael Brosch

Leibniz Institute for Neurobiology, Magdeburg, Germany

Definition

In psychology, the term *association* refers to a connection between different elementary mental entities (sensations, thoughts, feelings; Dudai 2002). Aside from innate, reflex-like associations, novel associations are typically acquired during learning. In Pavlovian/classical conditioning, a stimulus-stimulus association is formed by repetitively pairing an initially neutral stimulus with a biologically significant unconditioned stimulus that automatically triggers an unconditioned behavioral response. In instrumental/operant conditioning, a stimulus-response association is formed in the presence of reinforcers. Reinforcers can be either positive, such as water, food, money, and brain stimulation reward, and result in an increase in the probability of a response to the stimulus. Negative reinforcers (e.g., footshocks, airpuffs, money loss) decrease the probability of a response to the stimulus. If the reinforcer is removed, the learned associations risk extinction.

Detailed Description

Classical View of Brain Structures Reflecting Associations and Reinforcement

Traditionally associative functions are assigned to the so-called association cortex (Creutzfeldt 1983). Inspired by “associationism” (the philosophical doctrine that the mind learns and constructs the world bottom up by associating mental entities) and based on anatomical considerations, Flechsig originally defined the association cortex as that part of the cerebral cortex that appeared to lack direct afferences from the senses and efferences to peripheral motor structures. He proposed that the association cortex provides the substrate for the fusion of primary sensations to obtain ideas of objects as a whole. This idea is challenged, *inter alia*, by studies demonstrating associative functions already in primary sensory cortices, which have direct afferences from the senses. In addition, the sensory cortex is affected by reinforcement (Shuler and Bear 2006; Brosch et al. 2011a; Arsenault et al. 2013; Weis et al. 2013), which generally is thought to involve the limbic system, including the hypothalamus, amygdala, hippocampus, septal nuclei, ventral tegmental area, and anterior cingulate gyrus. These findings put into question the existence of unisensory cortical areas at all (Ghazanfar and Schroeder 2006).

Learning

Learning associations between stimuli, between stimuli and behavioral responses, or between stimuli and reinforcers change the auditory cortex, such as the feature sensitivity (spectrotemporal receptive field) of neurons in the auditory cortex, their response strength and response latency, as well as interneuronal synchrony (Scheich and Brosch 2013; Shepard et al. 2013). In detection tasks, the direction of the receptive field change at the frequency of the conditioned tone depends on the valence of the tone (Scheich et al. 2011); if it is negative (associated with punishment), the response to the tone is increased (receptive field is sensitized at the conditioned tone frequency); if it is positive (associated with reward), the response is decreased (receptive field is

suppressed at the conditioned tone frequency). In frequency discrimination tasks, slopes of spectral tuning curves become sharper around the conditioned frequencies. In categorization tasks, stimuli of the same category evoke (spatiotemporal) neuronal activity patterns that are more similar to each other than those evoked by stimuli of other categories.

These changes coincide with or may even form the basis of changes in representation maps (e.g., tonotopic frequency map) in the auditory cortex that occur, at least transiently, after learning (Shepard et al. 2013; Grosse et al. 2015). They may also underlie plasticity of neuronal mass activity, as revealed by electro- and magnetoencephalography (EEG, MEG) or functional magnetic resonance imaging (fMRI) (Rüsseler et al. 2005).

Neuromodulators

The formation of novel associations in the auditory cortex requires the involvement of neuromodulators (Shepard et al. 2013). Some of the described changes can also be mimicked by repetitively pairing auditory stimuli with electrical stimulation of neuromodulatory systems, such as the ventral tegmental area (dopamine; Huang et al. 2016a), the nucleus basalis of Meynert (acetylcholine; Bakin and Weinberger 1996), the locus coeruleus (norepinephrine; Martins and Froemke 2015), or the vagus nerve (triggering widespread release of neuromodulators; Engineer et al. 2011). Formation of associations in the auditory cortex also involves cognitive factors: changes in the auditory cortex and learning do not occur when an animal is passively exposed to the stimulus-reward pairings of another animal while it was instrumentally conditioned (Blake et al. 2006).

Neuronal Correlates of Association

Sustained firing and slow firing changes may provide neuronal correlates of associations between mental entities (Brosch et al. 2011a). The main condition necessary for the emergence of slow firing changes is that subjects have learnt that conditioned associations are contingent on reinforcers. When the reinforcer is removed, the slow

firing changes disappear within a few trials, concomitantly with behavioral changes (Huang et al. 2016b). These firings may be related to the contingent negative variation (Walter et al. 1964), an event-related potential that can be obtained in electroencephalography in humans. It is considered to reflect the contingency and the contiguity of two events that have a motivational “value.”

Different types of events may be associated through event-related slow firing changes (Brosch et al. 2011a). Events that trigger such changes can be auditory (and possibly visual) stimuli, reinforcers, and behavioral responses, like grasping. An event with which slow firing changes end is the reinforcer. Slow firing changes have been observed between (1) an auditory stimulus and a reinforcer, (2) a behavioral response and an auditory stimulus, and (3) a behavioral response and another behavioral response.

The association between behaviorally significant events provided by slow firing changes might even be directed in some cases, that is, this type of firing might provide some sort of either prospective coding of an upcoming event or retrospective coding about a preceding event.

Neuronal Correlates of Rewards

In animals actively engaged in listening to auditory stimuli, direct reflections of rewards have been demonstrated in the auditory cortex. Neuronal activity in the auditory cortex varied with the size of the delivered reward and the size of the reward that was expected to be earned in a future auditory task, as well as the magnitude of the mismatch between the expected and delivered reward (the reward prediction error) (Brosch et al. 2011b). Reflections of rewards are also present in other sensory cortices (Shuler and Bear 2006; Arsenault et al. 2013).

Definition

Attention – the ability of a sensory system to facilitate the processing of specific information at the expense of disregarding the remainder.

Bottom-up processes – information processing in the nervous system that operates in a feedforward way, advancing from sensory organs or areas at a low level of the cortical processing hierarchy.

Top-down influence – modulatory signals in the nervous system that originate from areas at a high level of the cortical processing hierarchy, influencing information processing in lower areas.

Saliency – a measure of the magnitude of the difference of a stimulus from its neighbors in space and time.

Detailed Description

The Case for Attention

Evolution has provided humans and other highly evolved species with powerful sensory systems. While our cortical processing capacity has also evolved and grown impressively, the torrent of information provided by our sensors far outstrips our ability to process it all. In addition, most of the sensory information picked up at any moment has little importance for our survival. Complex nervous systems faced with this challenge have developed sophisticated selection mechanism to identify the most relevant incoming information and to focus processing resources (and ultimately perception) onto this small fraction. This process is called attention and for the purpose of this entry can be defined as the selective modulation of sensory information based on its assumed behavioral relevance.

Bottom-Up Versus Top-Down

The selection processes underlying attention need to fulfill two requirements: on the one hand their ubiquitous (central and incessant) role in the continuous stream of perceptual decisions requires that they operate efficiently and as fast as possible. At the same time, the selection processes' purpose of dynamically identifying the most relevant components of the sensory input demands harnessing as much of the cognitive power of the species' central nervous system as possible.

These seemingly incompatible demands, efficient and fast vs. computationally demanding and thus slow, have created two flavors of selection:

1. A bottom-up (automatic, exogenous) attentional selection that exploits the realization that the most informative aspects of our sensory environments are those where one stimulus differs from their neighbors in space and time. This local saliency can be identified and enhanced by simple feedforward filter mechanisms embedded throughout the processing of sensory signals in the nervous system.

2. A top-down (voluntary, endogenous) attentional selection that integrates any information available to the organism about the current situation to make the most informed decision about which sensory input component represents the most relevant information in the given situation.

In the visual domain, this distinction is well illustrated with visual search tasks: If we are confronted with a fairly homogenous visual scene, any outlier will be identified, enhanced, and selected by the continuous parallel computation of local saliency, creating the perceptual “pop-out” characteristic of simple search tasks where the features of the target stimulus differ substantially from the distribution of features of the distractors. Conversely, a target stimulus, which is less distinct, either because it is defined as a conjunction of more than one feature or because it does not differ substantially from the distribution of distractor features, does not pop out, but rather requires a more demanding and correspondingly slower selection process.

Taking a Computational Approach to Attention

Here we illustrate how the attentional modulation of sensory information processing is implemented in computational models. Due to the brevity of the entry, we focus on a few examples of models of top-down attentional modulation in the visual system of man and other primates.

One of the most influential computational models of visual attention is the **feature integration theory** (FIT; Treisman and Gelade 1980). In the FIT, information about different features of stimulus, such as its shape, color, orientation, and movement, is extracted in parallel, automatically and effortlessly through a system of feature maps, which topographically represent the spatial distribution of specific features in the visual scene. This process detects and locates a target stimulus defined by a single unique feature value (such as the color red) because it is represented by a unique hotspot in a single feature map (with each

distractor represented by a hotspot in its corresponding feature map, such as the one for the color blue). This target detection is very quick and is unaffected by the numerosity of distractor stimuli, matching the experimental observation that human reaction times in such simple search tasks are independent of the number of distractor items. If the target stimulus is not defined by a single feature alone, but by a conjunction of multiple features, information from different feature maps needs to be integrated to detect and localize a target. This requires a serial process that actively integrates information from different maps to detect the target’s unique feature conjunction at one topographical location, matching the linear increase in reaction time observed with an increase in the number of distractors in a conjunctive search task. The FIT proposes that this serial integration process is accomplished by means of a top-down, spatial “spotlight” of attention.

An alternative account for the pattern of reaction times in search experiments is offered by the **guided search theory** (GST, Wolfe 1994), which does not assume an attentional spotlight. Instead, the top-down attentional signal changes the weight of activation maps before they are combined to create a ranking of all present stimuli based on their likelihood to represent a target. The selection of stimuli is then again performed serially, from high to low probability, until the target stimulus is detected.

While the FIT and the GST emphasize the role of feature maps in attentional selection, the **theory of visual attention** (TVA; Bundesen 1990) takes a different approach. Here the selection of stimuli is dependent on their processing speed. Before a stimulus can be encoded in visual short-term memory and thus enter awareness, it needs to compete in a computational race with other stimuli. In the TVA top-down attention speeds up the processing of certain items, making them likely to win the race.

While the FIT, GST, and TVA have been developed to account for the perceptual data available at the time, more recent models of attention have been developed to capture data from single-cell recordings from monkey visual cortex. Two early conceptual models attempted to account for the enhanced neuronal response to attended stimuli

and the reduced response to unattended stimuli. The **biased competition model** of attention (Desimone and Duncan 1995) envisages a competition between the stimulus representation of attended and unattended stimuli that can be biased by a top-down attentional signal in favor of the attended stimulus' representation. The **feature similarity gain model** of attention (Treue and Martinez-Trujillo 1999) alternatively proposes that the enhancement of neural responses by attention reflects a process where top-down attentional signals enhance the gain of those neurons whose preferred features match the current attentional state of the organism, independent of the stimulus that currently activates a neuron.

These two conceptual models have inspired a large number of computational models. The most prominent of those are models that emphasize an interaction of top-down attention with the normalization process that creates the sigmoidal contrast response functions typical for neurons throughout sensory cortex. Multiple varieties of such **normalization models** of attention have been proposed (Ghose and Maunsell 2008; Boynton 2009; Ghose 2009; Lee and Maunsell 2009, 2010; Reynolds and Heeger 2009). They all emphasize the similarity, in perception, as well as in the neural encoding and also in the central role of the response normalization process between two influences on the strength a neural stimulus representation. One is the physical (bottom-up) strength of the stimulus (most directly represented by its contrast) and the other is the attentional weight (implemented as a kind of sensory prior) assigned to them through a top-down attentional signal.

Beyond models that emphasize response normalization, there have been numerous other approaches to model the attentional modulation of sensory information processing. They include the **selective tuning model** (Tsotsos et al. 2005) that proposes a layered network architecture (representing the hierarchy of cortical areas) to implement a spatial "spotlight of attention" that endows certain regions of the visual scene with enhanced processing. The **spiking network model** (Deco and Rolls 2005; Deco and Thiele 2011) places much more emphasis than any of the models discussed above on building its approach

on biological components, such as spiking neurons and specific neurotransmitters.

The Integrated Saliency Map

It should be noted that almost all models of attention incorporate the concept of an **integrated saliency map** (Treue 2003), that is, a topographic representation of the stimuli in the current visual scene that combines their relative physical strength and their assumed behavioral relevance. This combination implements a weighing of bottom-up and top-down aspects of a stimulus, providing processing resources to strong unattended stimuli as well as to weak attended ones. While such an integrated saliency map. Is consistent with a number of perceptual phenomena and is ideally suited to guide eye movements across a visual scene, it is a matter of some debate which of the many topographically organized areas in the visual cortex represents this map or whether multiple such maps exist.

Similarly, while functional imaging and single-cell recording studies have implicated a network of frontoparietal areas in the guidance process that is necessary to appropriately allocate processing resources (Kastner and Ungerleider 2001; Corbetta and Shulman 2002), such anatomic specificity is rarely included in current computational models of attention.

Conclusion

In conclusion, in the last decade, a large number of computational models of top-down attention have been developed that can account for a large variety of perceptual and physiological aspects of the attentional modulation of sensory information processing. These models emphasize several core issues, such as the response normalization in cortical networks, the multistage nature of cortical information processing, and the concept of an integrated saliency map. Despite this progress much more work is needed to achieve a complete computational description of top-down attentional modulation.

Definition

Auditory brainstem responses (ABRs) are the earliest auditory event-related potentials (cf. ► [“Auditory Event-Related Potentials”](#)) elicited during the first 10 ms after stimulus onset in the anatomical relays of the auditory pathway. ABRs are typically recorded with scalp electrodes attached to the vertex and referenced to the earlobe or the mastoid. Two types of ABRs have been described: the transient-evoked responses and the sustained frequency-following response (FFR). While the transient-evoked ABRs are elicited to high-intensity clicks or tone bursts, FFRs can only be recorded to periodic auditory stimuli, and their duration extends to the length of the eliciting sound. In the ABRs elicited to periodic and complex auditory stimuli,

such as speech sounds or music, the two types of ABRs can be observed.

Detailed Description

Transient-Evoked ABRs

The first systematic observation of the human transient ABRs was by Jewett, Romano, and Williston in 1970 (Jewett et al. 1970; Jewett and Williston 1971) who described a series of six or seven fully visible waveforms spanning the first 10 ms after sound onset. ABRs are characterized for being fast, vertex-positive response peaks spaced at intervals of about 1 ms and are evoked by brief stimulus features, such as broadband clicks, tone bursts, or the abrupt onset of a sound (Pratt 2012).

The different ABR waveforms define a very characteristic morphology and are labelled in sequence by Roman numerals from I to VI (Fig. 1). Their amplitude is in the order of tenths of a microvolt, smaller than 0.5 mV (Pratt 2012), with the most positive component being wave V (Picton 2011; Pratt 2012). The first component of the sequence, wave I, is the most positive peak occurring at approximately 1 ms after stimulus onset and corresponds to the N1 wave of the

Auditory Brainstem Responses, Fig. 1 Morphology of the human transient ABR. The figure depicts the typical morphology of a healthy human adult ABR. It was obtained by averaging the responses to 6000 presentations of a click delivered bilaterally at 85 dB SPL at a rate of 19.3/second. The recording is between electrodes placed at FPz and the right mastoid. The EEG was acquired at 20 kHz sampling rate using a band-pass filter from 100 to 3000 Hz. Waves I to VI are identified at their typical latencies

electrocochleogram. Between waves I and V, the most prominent deflection is wave III, which occurs at a latency of about 3.5 ms. Wave II is a small peak halfway between wave I and III, and waves IV and VI can be observed in both sides of wave V. Wave IV is not always identified in humans, and when present it is often merged partially with wave V, yielding a wave IV-V complex (Picton 2011; Pratt 2012).

The different ABR components are generated by distinct anatomic structures of the auditory pathway. The first components of the sequence, waves I and II, are generated exclusively by the auditory nerve (Gelfand 2010). More precisely, wave I originates in the ipsilateral distal portion of the auditory nerve in the region of the ganglion cells and wave II from the ipsilateral proximal portion of the auditory nerve in the vicinity of its entry into the brainstem (Stone et al. 2009; Pratt 2012). The later components, waves III, IV, and V, have contributions from more than one anatomical structure. Wave III has been attributed to the region of the ipsilateral cochlear nucleus and the superior olivary complex (Stone et al. 2009; Picton 2011). The generators of wave IV are still under debate, but all evidence points to bilateral multiple brainstem sources (Stone et al. 2009), between the superior olivary complex through the lateral lemniscus, with a possible contribution from the inferior colliculus (Pratt 2012). Wave V is originated in the contralateral distal lateral lemniscus and the inferior colliculus (Stone et al. 2009), so overall, the wave IV-V complex is attributed to bilateral generators in the region of the midbrain tegmentum (Starr et al. 2008). Wave VI has been attributed to the medial geniculate body (Gelfand 2010). Although these sources are the most accepted ones across the literature, there are still divergent opinions regarding the exact origins of the components from wave II onwards, as it is known that multiple generators in the auditory brainstem may be contributing to them (Gelfand 2010; Picton 2011).

The transient ABRs are typically elicited by broadband clicks or chirps (Fobel and Dau 2004; Maloff and Hood 2014) presented at a rate ranging from 10 to 20 stimuli per second. They are optimally recorded from the scalp with an electrode at

the vertex of the head (Cz or Fz) referenced to an electrode in the vicinity of the stimulated ear (mastoid or earlobe). To extract the ABR from the auditory evoked potential, a frequency band-pass filter from 30 to 3000 Hz is necessary, and, due to the small amplitude of the components, an average of at least 2000 stimulus presentations is required. The sampling rate of the electroencephalographic signal should not be lower than 20 kHz to avoid waveform distortions (Picton 2011; Pratt 2012). When measuring ABRs, the stimulus polarity must also be taken into account, as although the full set of components can be obtained with stimuli presented in any polarity (i.e., condensation and rarefaction), the latency of the different components is modulated depending on it (Ballachanda et al. 1992; Hall 2007).

A range of non-pathological factors affect the transient ABR, such as subject's age, gender, and body temperature. Also, stimulus factors like intensity or presentation rate do affect the recorded ABR (Picton 2011; Pratt 2012); a typical example is the shortening of the ABR peak latencies by increasing stimulus intensity. On the other hand, the ABR has high sensitivity, specificity, and reliability, and it is not susceptible to the evoking stimulus being attended or ignored nor to changes during sleep or under anesthetics (Picton 2011). Fields of clinical application of ABR recordings are, among others, newborn and infant auditory screening (i.e., the estimation of auditory sensitivity in infants and difficult-to-test children) and neurodiagnosis of eighth nerve or auditory brainstem dysfunction (i.e., monitoring eighth nerve and auditory brainstem status intraoperatively during surgery potentially affecting the auditory system and the diagnosis of auditory neuropathy) (Hall 2007).

Frequency-Following ABRs

The frequency-following response (FFR) is a component of the auditory brainstem response that reflects sustained and synchronous neural phase-locking to the individual cycles of the eliciting stimulus waveform and/or to the periodicity in the envelope of an acoustic stimulus (Skoe and Kraus 2010; Kraus et al. 2017). The scalp-recorded FFR can be evoked by frequencies

in the range of 100–1500 Hz approximately. By reflecting the phase-locked activity to sounds, the FFR physically “mimics” the eliciting stimulus and is as complex as it, thus providing a stable window into the neural transcription of sounds in neuronal aggregates along the auditory hierarchy (Galbraith et al. 2000; Bidelman 2018).

The FFR was first recorded in humans by Moushegian, Rupert, and Stillman in 1973 (Moushegian et al. 1973), and it is suggested to represent phase-locked neural activity from multiple generators within the auditory system. Currently, the neural origins of FFR are still debated, yet it is treated as a putative window into subcortical sound encoding. The FFR can be obtained under passive and active listening paradigms, and it is highly sensitive to context-dependent contingencies and to real-time statistical properties of the stimulation sequence. It is also modulated by short-term auditory training and by the individual's lifelong auditory experience, such as that with language and music. Consequently, the FFR has become a relevant tool in assessing the neural encoding of speech sounds in both healthy and clinical populations (Escera 2017; Kraus et al. 2017).

By means of the appropriate analytical tools, the FFR provides an objective indicator of fundamental acoustic features intrinsic to speech and other complex sounds, including timing (onsets), pitch (fundamental frequency, f_0) and timbre (the harmonics information), as well as their timing (see Kraus et al. 2017).

Auditory Cortex: Separating Signal from Noise

Brian Malone

Department of Otolaryngology and Head and Neck Surgery, University of California, San Francisco, CA, USA

Synonyms

[Auditory scene analysis](#); [Auditory scene segmentation](#)

Definition

The process of separating signal from noise is an aspect of the process of auditory scene segmentation in which the pressure waves from multiple, concurrent sound sources that mix in the air must be de-mixed by perceptual processes to generate an auditory object-based model of sound sources in the environment. Sounds that interfere with the detection or discrimination of an informative sound of interest, the signal, are often described as noise. The use of the term “noise” is informed by a long history of psychophysical experiments that measure the adverse effects of adding sounds, usually based on stochastic processes, to more behaviorally relevant signals, such as speech. Neurophysiological experiments have demonstrated that brain regions that process sound act to filter out noise while retaining information about behaviorally important sounds, such that the neural representations of sound mixtures in central structures like auditory cortex are significantly de-noised relative to representations of those sounds in more peripheral brain regions, such as the cochlear nucleus. The effects of background noise on neural responses to a signal depend on the relative amplitudes of the signal and noise, which is typically quantified in terms of the signal to noise ratio (SNR), in decibels. The similarity between signal and noise in terms of frequency content, temporal pattern, and spatial location have important implications for how

much noise at a particular SNR will disrupt processing of the signal. Neurophysiological recordings from auditory cortex have demonstrated significant diversity in how background noise affects cortical responses to certain classes of signals, including cases where noise at moderate SNRs can enhance the cortical representation of some signals.

Detailed Description

Perceptual segmentation of complex scenes relies on assigning the most likely distribution of sound sources based on the mixtures of sounds arriving at the ears (Bregman 1990; Yost 1992). Most naturally occurring sounds are complex and time-varying, so the auditory system must not only correctly attribute acoustic energy at different frequencies to a single sound source, but, in the presence of multiple concurrent sounds, must often parse acoustic energy at a single frequency among multiple sources. When thinking about this process, it is often useful to categorize sounds as “signal” or “noise” with respect to the listener’s specific goals. For example, on a busy street, the sound of passing cars is noise that interferes with the conversation between two pedestrians. However, the pedestrians’ conversation can also be noise that interferes with the ability a nearby bystander listening for the sound of passing cars to determine whether it is safe to cross the street. The term “background noise” is often contrasted with “foreground sound” to indicate the attentional focus of the listener.

Although the neurophysiological literature sometimes makes reference to intrinsic noise that results in variable neural responses across repeated presentations of identical stimuli, for the purposes of this entry, “noise” should be understood to refer to external, physical sounds that disrupt the processing of another sound. Traditionally, the sounds used as background noises in studies of cortical responses tend to be stochastic in nature, and as such, are defined by their time-averaged statistics, rather than a specific time-frequency pattern. For example, broadband or “white” noise has a flat spectrum over the audible range when measured over a sufficiently

long interval, but the spectra of short segments of white noise vary considerably, and the output of a filter with a narrow bandwidth will show considerable modulation over time. These considerations are important when considering the expected responses of cortical neurons. In primary auditory cortex, for example, sharply tuned neurons with short temporal integration windows can exhibit highly reproducible, time-locked responses to repeated presentations of an identical (“frozen”) instance of broadband noise (Scott et al. 2011). In fact, humans in laboratory settings distinguish among distinct instances of broadband noise (Agus et al. 2010). In natural listening conditions, however, the exact time-frequency patterns of environmental noise sources such as wind or ocean waves do not repeat and are not perceptually meaningful beyond their adverse effects on the processing of more behaviorally relevant signals (McDermott et al. 2013).

We define the neural representation of a stimulus as the pattern of activity that occurs in response to the stimulus and conveys information about that stimulus to auditory structures further along in the processing pathway. Background noise can corrupt the signal representation by eliciting responses that would otherwise not occur, or by reducing or eliminating responses that are typically elicited by the signal. Effectively, signals and noises compete for neural representation by influencing the patterns of neural activity in a given auditory area. It is possible that changes in signal representations might not necessarily interfere with perceptual discrimination if those changes are small relative to the differences in the responses to a set of distinct signals. Central auditory representations of complex sounds have been described as “noise invariant” (Moore et al. 2013; Rabinowitz et al. 2013) when response features associated with the signals are preserved while those associated with the noise are attenuated at successive stages of the auditory pathway.

Early studies that measured auditory cortical responses to simple stimuli such as pure tones containing a single frequency tended to focus on how tuning curves that relate neural firing rates to signal amplitude shift in the presence of additional background noise (Ehret and Schreiner 2000;

Phillips 1990; Phillips and Cynader 1985; Phillips et al. 1985) and have typically reported increases in response thresholds and latencies. Studies that have employed complex, time-varying signals have considered how the pattern of cortical responses changes in the presence of noise. For example, background noise reduces synchronization to the phrases of primate vocalizations (Nagarajan et al. 2002) and birdsong (Narayan et al. 2007).

Despite increasing research focus on cortical signal in noise processing (Bar-Yosef and Nelken 2007; Schneider and Woolley 2013), important questions remain about the underlying neural mechanisms. Proposed mechanisms include spectrotemporal filtering (Lee and Theunissen 2015), adaptation (Rabinowitz et al. 2013), synaptic depression (Mesgarani et al. 2014), and feedback gain normalization (Mesgarani et al. 2014). Recent studies have demonstrated additional complexities in how cortical neurons encode signals in noise. Similar to perceptual studies, the adverse effects of background noise at a given SNR depend on the absolute levels of both the signal and noise, such that loud noise is more disruptive than moderate noise at equivalent SNRs (Teschner et al. 2016). Among distinct clusters of cortical neurons, background noise can disrupt, fail to affect, or even enhance the representation of frequency-modulated sweeps, even in animals that are not required to attend to the stimulus (Malone et al. 2017).

Importantly, auditory cortex spans multiple levels of processing in the auditory pathway. In humans and many other vertebrate animals, the auditory cortex is comprised by a number of areas in the temporal lobe of the brain. In primates, including humans, auditory cortex is organized into core areas which receive direct projections from the ventral division of the medial geniculate body and then project to belt areas that project, in turn, to parabelt areas. Because cortical responses are believed to be more modulated by attentional mechanisms and more plastic in response to sensory exposure and perceptual learning than more peripheral structures, the question of how auditory cortical regions represent signals of interest in the presence of competing sounds is of special relevance. The balance of “bottom-up” mechanisms

acting on sensory input and “top-down” mechanisms engaged by attentional focus likely shifts at different levels of the cortical processing hierarchy (Niwa et al. 2013, 2015).

Separation of signal from noise is of great clinical relevance, since the inability to follow ones stimulus among many, the “cocktail party problem” (Cherry and Bowles 1960; Cherry and Wiley 1967; Plomp 1977) is a hallmark of hearing loss, and among the most common hearing complaints in the elderly. Neurophysiological experiments in older animals suggest that reductions in the strength of inhibition may prevent the appropriate suppression of background noise (Presacco et al. 2016; Recanzone 2018).

Auditory event-related potential (AERP); Auditory evoked field (AEF); Auditory evoked potential (AEP)

Definition

Auditory event-related potentials are electric potentials (AERP, AEP) and magnetic fields (AEF) generated by the synchronous activity of large neural populations in the brain, which are time-locked to some actual or expected sound event.

Detailed Description

Measurement and Derivation of AERPs/AEFs

AERPs are derived from the continuous electro-/magnetoencephalogram (EEG/MEG) by extracting segments of the signal (epochs) time-locked to some actual or expected acoustic event. AERPs were first recorded by Hallowell and Pauline

A. Davis in 1935–1936 (Davis 1939; Davis et al. 1939). Because EEG/MEG is typically recorded non-invasively (outside the brain, e.g., from/around the scalp), these measures only reflect synchronous activity of large neural populations (for measuring methods and instrumentation). Consequently, the acoustic events eliciting detectable AERPs consist of relatively large changes of spectral energy occurring within a relatively short time period, such as abrupt sound onsets, offsets, and changes within a continuous sound, because large acoustic changes affect many neurons within the auditory system and the short transition period synchronizes the responses of individual neurons (Nunez and Srinivasan 2006; cf. ► “Anatomy and Physiology of the Mammalian Auditory System”). Furthermore, the expectation of such changes in the auditory input can elicit AERP responses even in the absence of actual stimulation (cf. the *Omitted Stimulus Response* in “Long-Latency AERP Responses,” below).

The EEG/MEG signal mixes together on-going (spontaneous) neuroelectric activity with that elicited by the event. In order to better estimate the brain activity evoked by the event, it is usually repeated several times (typically 50–200 trials/sweeps, but up to 2000 times for ► “Auditory Evoked Brainstem Responses”) and the EEG/MEG segments are entered into some mathematical algorithm extracting the common part of the single-trial epochs. The most commonly used method for extracting AERPs aligns the single-trial epochs by their common onset and averages them point by point (the averaging method; Alain and Winkler 2012). There are many other algorithms for extracting ERPs from EEG/MEG, each based on different assumptions regarding the properties of the event-related response and the spontaneous EEG/MEG activity (for a general primer, see Luck 2005; for detailed discussion of ERPs, see Handy 2005; Fabiani et al. 2007; for special considerations of MEG/AEFs, see Hansen et al. 2010; Nagarajan et al. 2012; for AERPs, see Picton 2010; Alain and Winkler 2012).

EEG/MEG signals can contain components up to a few kHz with the faster components mainly originating from lower levels of the auditory

system (cf. ► “Anatomy and Physiology of the Mammalian Auditory System” and ► “Auditory Evoked Brainstem Responses”). Cortical contributions are much slower, up to a few tens of Hz. Unless one is specifically looking for very slow (Vanhatalo et al. 2005) or fast responses (Curio 2005), AERP recordings are usually made with bandpass filter settings of 0.01–50 Hz (or 250 Hz for extracting the Middle-Latency Response, see below). AERP amplitudes are typically below 10 μ V with the reference (zero) level set to a baseline voltage (unless direct current is recorded), which is usually the average signal amplitude in a time interval preceding the AERP-eliciting event. Although in general, there is no unique solution to the inverse problem of finding the origins (the neural generators) of electromagnetic potentials measured outside the brain, by utilizing anatomy/physiology based constraints, the generators of AERPs can be located with reasonable accuracy in the brain (Nunez and Srinivasan 2006; see also ► “Brain Imaging: Overview”). Due to the underlying physics, magnetic AEFs provide more accurate source localization compared with electric AERPs (Nunez and Srinivasan 2006; Nagarajan et al. 2012). On the other hand, MEG only allows one to measure the tangential components of the electromagnetic activity in the brain, whereas EEG represents the full activity (Hansen et al. 2010). For AEFs, however, this limitation of the MEG signal is less severe than for other sensory/cognitive systems (Picton 2010; Nagarajan et al. 2012). This is because a large part of the human auditory system in the cortex is located in the Sylvian fissure (see ► “Anatomy and Physiology of the Mammalian Auditory System”), thus mostly producing magnetic signals which can be picked up by the MEG device.

AERP Waves, Components, Naming Conventions

Figure 1 illustrates the progression of stimulus-related neuronal activity through the auditory system and the corresponding series of positive and negative waveforms observable in the AERP response. The earliest detectable responses (< ca. 10 ms after the acoustic event) originate

Auditory Event-Related Potentials, Fig. 1 The human Auditory Event-Related Potential (AERP), its main waveforms and its generators in the brain. The human AERP is composed of three groups of waveforms in three different latency ranges: the Auditory Brainstem Response (ABR) elicited within the first 8–10 ms from sound onset (*green, bottom panel*); the Middle-Latency Response (MLR), elicited within the 12–50 ms interval from sound onset (*blue, central panel*), and the Long-Latency Responses (LLR) emerging after 50 ms (*red, top panel*). The anatomical inset (*left panel*) highlights the main stages of the

auditory pathway: “bn”, brainstem nuclei (including the cochlear nucleus, the superior olivary nucleus, the nucleus of the lateral lemniscus); “IC”, inferior colliculus; “MGB”, the medial geniculate body in the thalamus; “AC”, auditory cortex. The main assumed brain sources of the different AERPs are marked by colored circles: the ascending auditory pathway of the brainstem for ABRs (*green*); the thalamo-cortical loops and parts of auditory cortex for MLRs (*blue*); the auditory cortex for LLRs (*red*). AERPs can be broken down into a series of waves (see the naming convention in the main text)

from subcortical brain structures and are termed the *Auditory Brainstem Response* (ABR; cf. ► “*Auditory Evoked Brainstem Responses*”). These are followed by AERP responses of thalamo-cortical origin (mainly from the primary auditory cortex), termed the *Middle-Latency Response* (MLR), elicited during the ca. 10–50 ms post-event latency range. The waveforms following are called *Long-Latency Responses* (LLR) and they originate largely from auditory cortex, but may also include contributions from parietal and frontal areas.

ABRs are referred to by Roman numerals set in the order of their elicitation. MLR waveforms are usually denoted by their polarity at the vertex (approximately the top of the head); P for positive and N for negative polarity waves, and a letter or a number (see Fig. 1). There are two conventions for the numbers in referring to LLRs: They either denote the serial order of the response starting with the first detected response (Davis 1939; Davis et al. 1939), termed N1, or they denote the typical peak latency of the waveform, such as P50 (the same as Pb or P1). However, as more and

more responses elicited with the same polarity and in overlapping latency ranges have been discovered, both notations have become equivocal. Therefore, some recently discovered AERP responses are denoted by acronyms referring to their functional aspects, such as ORN (Object Related Negativity) or MMN (Mismatch Negativity) (for a detailed description of the variety of ERP responses, see Luck and Kappenman 2012; for AERPs, Picton 2010; Alain and Winkler 2012). Magnetic response fields are usually marked by the letter ‘m’ appended to the name of the corresponding (A)ERP (e.g., N1m or N100m).

Beyond the categorization based on the ERP peak latency there are two other typical distinctions in use. ERPs are termed obligatory or exogenous if they are elicited by each event irrespective of its relation to preceding or concurrent events or the person’s task, motivations, knowledge, etc. ERP components elicited only when there is a certain relation between the event and other events or some aspect of the person’s mental state are termed endogenous. Another distinction refers to the person’s voluntary activity with respect to the given stimulus event. ERP responses only elicited when the person has some explicit task involving the event (task-relevant even) are termed “active” ERP responses, while those elicited irrespective of the person’s task (task-irrelevant) are termed “passive” ERP responses.

However, waveforms (peaks and dips) are not the true building blocks of ERP responses. The brain is a massively parallel processing instrument. Therefore, at any given moment of time, multiple processes may contribute to the observable waveform. For a neurophysiologically and functionally more meaningful decomposition of the complex neuroelectric response, one should be able to delineate how each of the concurrent processes contributed to the observed neuroelectric activity. This objective is reflected by Näätänen and Picton’s (1987) definition of an ERP component: ‘... we define an EP “component” as the contribution to the recorded waveform of a particular generator process, such as the activation of a localized area of cerebral cortex by

a specific pattern of input’ (p. 376). Thus a component is defined by two criteria: (1) it should have a specific generator structure (e.g., secondary auditory and frontal cortices) and (2) it should be specific to some experimentally definable stimulus configuration (such as stimulus change after several stimulus repetitions). One could amend this definition with the person’s task/goals/knowledge regarding the given stimulus configuration (e.g., instructed to respond to the given stimulus event). However, the criteria set up by the above definition are seldom met in ERP research. This is partly due to limitations in separating generators (i.e., they are usually distributed over an area in the brain and concurrently active processes often occupy areas very close, possibly even overlapping each other) as well as not knowing what stimulus configurations are handled by the same processes in the brain (are all expectation violations processed in the same way? – probably not). Thus in practice, the majority of ERP research reports use the terms “waveform” and “component” interchangeably, sometimes linking the effects of multiple manipulations to the same waveform, while at other times, attempting to separate the specific generator process affected by a given stimulus or state variable.

There are many different processes, which can be reflected in AERPs. Early, obligatory responses typically reflect processes extracting auditory features, such as pitch, intensity, location, etc. Most AERP responses are sensitive to the amount of sound energy change and also to some aspects of the sound presentation rate or the ratio between sound and silence in time. These attributes of auditory stimuli belong to the primary descriptors of sound events as studied in psychoacoustics (Zwicker and Fastl 1990). There are also AERP responses indicating the presence of automatic memory for sounds (Cowan 1984; Demany and Semal 2007) and predictive processing of the auditory input (Friston and Kiebel 2009; Winkler et al. 2009). Further, some AERP responses reflect processes involved in auditory scene analysis (Bregman 1990), the separation of concurrently active sound sources in the environment and the formation of auditory perceptual objects (Griffiths and Warren 2004; Winkler

et al. 2009). Many AERP responses are also sensitive to attentional manipulations, including the active storage of sounds, selective attention, and target identification (Cowan 1988; Näätänen 1990). AERP responses specific to music and speech perception are described in the corresponding entries (► “Music Processing in the Brain” and ► “Electrophysiological Indices of Speech Processing”). Therefore, AERPs have been extensively used to test theories of perception (e.g., Bregman 1990; Friston 2005), memory (e.g., Broadbent 1958; Baddeley and Hitch 1974; Cowan 2001), and attention (e.g., Broadbent 1958; Lavie 1995) and in recent years they have received increased interest from computational modelling (e.g., Garrido et al. 2009; May and Tiitinen 2010; Wacongne et al. 2011) as well as from clinical applications (e.g., Picton 2010; Näätänen et al. 2012).

In the following, we shall describe the most important middle- and long-latency AERP responses (for the auditory brainstem responses, see ► “Auditory Evoked Brainstem Responses”).

Middle-Latency AERP Responses

Discrete auditory stimuli elicit a sequence of very small (<1 μ V) negative and positive waveforms in the 10–50 ms post-stimulus latency range, termed the Middle Latency Response (MLR). These responses can usually be best seen on signals recorded from the vertex with a mastoid or neck electrode as reference. The names and typical latencies of MLRs when elicited by click stimuli are: *N0* (10 ms), *P0* (15 ms), *Na* (20 ms), *Pa* (30 ms), and *Nb* (~40 ms) (see Picton 2010). An additional later waveform, the *Pb*, which peaks at about 50 ms from sound onset, is not always included amongst the MLR components, because it can also be obtained as the P50 or P1 with the filter bandwidth optimised for measuring LLRs (Regan 1989; see below). Because of their small amplitude and specific spectro-temporal characteristics, recording the MLR requires (a) averaging across close to 1000 responses, (b) appropriate filter settings (15–200 Hz, Bell et al. 2004), and (c) careful removal of

electromagnetic interference from power supplies and lines, as a large part of the power of the MLR responses falls into the 50–60 Hz range. It is also important to avoid artefacts stemming from the myoelectric activity of the postauricular muscle (PAM), which lies behind the ear and is activated by loud sounds. This is usually achieved by placing the reference electrode on the neck or the sternum (Bell et al. 2004). Optimal sounds for eliciting clear MLRs are chirps and clicks, which have sharp onsets and a broad spectrum. Pure tones elicit MLRs of somewhat different morphology and smaller amplitude (Borgmann et al. 2001). However, MLRs can be obtained even with low-intensity tone bursts and relatively independently of the arousal level (Jones and Baxter 1988).

No hemispheric asymmetry was found for MLRs as a function of the stimulated ear (Starr and Don 1988). Based on precise structural maps of individual brains, the spatiotemporal pattern of neural activation giving rise to MLRs has been identified in supratemporal auditory areas using either current estimates derived from intracerebral recordings (Yvert et al. 2005) or equivalent dipole source modelling of scalp-recorded electric brain potentials (Yvert et al. 2001). These studies localized the earliest cortical activity (P0) at 16–19 ms from sound onset in the medial portions of Heschl’s sulcus (HS) and Heschl’s gyrus (HG), which likely correspond to primary auditory cortex (PAC). Na generation resulted from activity in more posterior regions of the same HS and HG areas. During the Pa/Pb complex, which includes also the Nb, the electric brain activity propagates in postero-anterior and medio-lateral directions in HG to the Planum Temporale (PT) and then to more anterior parts of the Superior Temporal Gyrus (STG), which correspond to secondary auditory areas. Also, frontal and parietal brain regions contribute as early as 30 ms from sound onset (the P30 m AEF response) to MLR (Itoh et al. 2000). Animal studies have suggested that MLRs involve parallel thalamocortical activation of areas 41 (PAC), and 36 (parahippocampal gyrus), while human lesion studies have implicated contributions from thalamic projections to Pa (Kraus et al. 1982) and Na (Kaseda et al. 1991),

supporting a thalamo-cortical interaction in MLR generation.

With increasing sound intensity, MLR component latencies decrease while the amplitudes increase, although these effects may not uniformly apply to each component (e.g., Na, but not Pa; Seki et al. 1993; Althen et al. 2011). Galambos et al. (1981) found a systematic reversed U-shaped relationship between the MLR amplitudes and stimulus presentation rate. At slow rates (≤ 10 Hz), peak-to-trough amplitudes are rather small (0.4 μ V) and they reach the maximum of 1 μ V by about 40 Hz presentation rate. This twofold increase in amplitude is due to superimposition of MLRs elicited by successive sounds. In contrast, at stimulation rates below and above 40 Hz out-of-phase responses to successive MLR responses cancel out each other. Some authors interpret this finding in terms of the “steady state” potentials (oscillatory activity generated in sensory cortical areas that is time-locked to the periodicity of stimulus presentation; typically measured from visual and somatosensory cortical areas; Rees et al. 1986). Other authors assume that this phenomenon reflects the contribution of transient early evoked gamma-band oscillations to the auditory MLR (Basar et al. 1987; Pantev et al. 1991; Müller et al. 2001). Based on the stimulus-driven properties outlined above, MLRs have been considered exogenous AERP components. However, this view has been challenged by studies showing that MLRs are enhanced by strongly focused attention as early as 20 ms from sound onset (Woldorff and Hillyard 1991; Woldorff et al. 1993; cf. “Attention-Related AERP Responses” below), and that MLR amplitudes are modulated as early as 50 ms from sound onset by task difficulty and whether or not a motor response is required (Ninomiya et al. 1997). Further, a recent series of studies has shown that MLRs are sensitive to stimulus probability in a feature-specific manner (Grimm and Escera 2012) with infrequent frequency changes enhancing the Pa (Slabu et al. 2010) and Nb (Grimm et al. 2012; Alho et al. 2012), whereas location changes enhance the Na (Sonnadara et al. 2006; Grimm et al. 2012; Cornella et al. 2012). These results suggest that the MLR components reflect processes

subserving higher-order sensory/cognitive functions.

Long-Latency AERP Responses

The auditory *P1* (*P50*, *Pb*; Fig. 1) component is at the border between MLR and LLR. In fact, when recorded and analysed with the filter setting most useful for deriving MLRs it is termed the *Pb* (see “Middle-Latency AERP Responses,” above). Using the parameters better suited for assessing LLRs, it typically peaks at about 50 ms from stimulus onset, appearing with positive polarity at the vertex and with reversed (negative) polarity at electrodes placed on the other side of the Sylvian fissure (e.g., electrodes placed over the mastoid apophysis). *P1* is the first wave of the *P1-N1-P2* obligatory exogenous AERP complex. It is thought to be generated bilaterally in primary auditory cortex, somewhat larger contra- than ipsilaterally for pure tones (Godey et al. 2001) and for other types of pitch-evoking sounds (Butler and Trainor 2012), with some spreading of the neuroelectric activity over its time course (Yvert et al. 2005). *P1* is often used as a landmark for primary auditory cortex in AERP and AEF studies aimed at localizing the AERP components. Similarly to other obligatory AERP responses, *P1* is highly sensitive to stimulus features and presentation rate (fully recovering within a few hundred milliseconds) as well as to attentional manipulations (Picton 2010). The *P1* was initially assumed to reflect neural activity involved in extracting auditory features (e.g. Näätänen and Winkler 1999). Recent evidence also links this response with the automatic separation of auditory streams (Gutschalk et al. 2005; Snyder et al. 2006; Szalárdy et al. 2013; cf. ► “Auditory Perceptual Organization”): The amplitude of the *P1* component has been found to be modulated by whether a sequence with two interleaved sounds (e.g., ABABAB... , where ‘A’ and ‘B’ denote two different sounds) was perceived as a single coherent stream or in terms of two concurrent streams of sound (one made up of the ‘A’ and the other by the ‘B’ sounds).

The auditory *N1* (*N100*; Fig. 1) wave was the first AERP response discovered historically (Davis et al. 1939) as it is the most prominent

deflection at the vertex. It is elicited by abrupt changes in sound energy, such as sound onsets and offsets (Näätänen and Picton 1987). N1 typically peaks with negative polarity over the vertex ca. 100 ms after the eliciting event. It is also the most widely studied AERP response, having been linked with virtually any and all assumed auditory processing steps. The N1 wave has a complex generator (and thus subcomponent) structure (Näätänen and Picton 1987). The subcomponent most tightly related to auditory processes (the supratemporal N1) is mostly located in secondary auditory areas (Godey et al. 2001), but it also overlaps the areas active during the P1 component (Yvert et al. 2005). Similarly to the P1, N1 is larger contralaterally to the ear of stimulation and it is highly sensitive to stimulus features, presentation rate, and attentional manipulations. However, unlike the P1, the N1 recovery is much slower, extending beyond 10 s (Cowan et al. 1993). Further, N1 is sensitive to perceived sound features (e.g., pitch), as opposed to raw spectral parameters (such as the harmonic frequencies of a complex tone; Pantev et al. 1989b), although feature extraction is not yet complete at the time the N1 wave is elicited (Winkler et al. 1997). The supratemporal N1 also shows both tonotopic (Pantev et al. 1988) and amplitopic organization (Pantev et al. 1989a); that is, the location of its generator varies with the frequency and amplitude of pure tones. However, the N1 generators are not sensitive to combinations of sound features (i.e., feature conjunctions).

The processes reflected by N1 have been linked with onset and acoustic change detection (Näätänen 1992), feature extraction, sensory memory (Lü et al. 1992; at least for sound features, Näätänen and Winkler 1999) and, recently, with auditory stream segregation (Gutschalk et al. 2005; Snyder et al. 2006; Szalárdy et al. 2013). For example, the length of the silent period after which an N1 with maximal amplitude is elicited by a sound is in good correspondence with the behaviourally measurable duration of auditory sensory memory traces (Cowan 1984). When sounds are presented in a train with <10 s silent intervals between them, the N1 amplitude

decreases sharply within the first few presentations, reaching an asymptote within 5–10 presentations (e.g., Cowan et al. 1993). Based on this finding, some authors argue that through adaptation (see ► [“Adaptation in Sensory Cortices, Models of”](#)), the neurons underlying the N1 response may retain all sound information and thus provide the basis for detecting violations of auditory regularities (May and Tiitinen 2010). However, this hypothesis is debated in the literature (e.g., Näätänen et al. 2011). The sensitivity of the auditory N1 wave to selective attention initially suggested that the difference between the N1 responses elicited by task-relevant (attended) and task-irrelevant (unattended) sounds (the Nd; Hillyard et al. 1973) may reflect an orientation to the attended auditory features and/or maintenance of the memory trace of the target sound. However, others argued that the differential response is separate from the N1, with the early part overlapping the N1 (termed Nd_e) assumed to reflect feature processing, and the later part (Nd_i, also termed the Processing Negativity, PN; Näätänen 1982; see PN in [“Attention-Related AERP Responses”](#)) the maintenance of the attentional trace (Koch et al. 2005; Näätänen et al. 2011).

Little is known about the auditory P2 (P175, P200; Fig. 1) AERP response. It has been mostly studied within the P1-N1-P2 or N1-P2 complex. P2 typically peaks between 175 and 200 ms from the event onset with positive polarity over the vertex, inverting polarity over the Sylvian fissure. The generators of P2 lie anterior to those of the N1 in secondary auditory areas (Mäkelä et al. 1988; Bosnyak et al. 2004). Lesion (Woods et al. 1993) and maturation studies (Ponton et al. 2000) suggest that P2 may reflect the output of the mesencephalic reticular activating system (see ► [“Anatomy and Physiology of the Mammalian Auditory System”](#)). Only a few studies have attempted to distinguish P2 from the N1 wave. The P2 amplitude was found to be more sensitive to perturbing the feedback of one’s voice than the N1 (Behroozmand et al. 2009) as well as to training with specific types of sounds (e.g., speech: Tremblay et al. 2001; music: Bosnyak et al. 2004; or frequency discrimination: Tong et al. 2009). There are several speculations regarding

the functions of the processes reflected by P2. Based on its assumed neural origin, P2 has been suggested to be generated by a pre-attentive alerting mechanism (Tremblay and Kraus 2002). Other suggestions include P2 reflecting stimulus classification (Crowley and Colrain 2004), modulating the threshold for conscious perception (Melara et al. 2002), protecting against interference from irrelevant stimuli (Garcia-Larrea et al. 1992), and the accuracy of memory traces in short-term memory (Atienza et al. 2002).

The *Object Related Negativity* (ORN) is elicited when more than one sound are simultaneously heard (Alain et al. 2001). Thus ORN reflects the outcome of the analysis of simultaneous (concurrent or vertical) auditory grouping

cues (cf. ► “Auditory Perceptual Organization”). Components of sounds emitted by a single source usually commence at the same time, they originate from the same spatial location and, if composed of discrete frequencies, they consist of harmonics derived from the same base (i.e., integer multiples of the same frequency). When the acoustic input does not meet these criteria, one usually experiences it as two or more concurrent sounds and ORN is elicited. ORN is typically recorded by presenting complex tones with one harmonic mistuned by 4% or more (Fig. 2, panel A) and derived by subtracting the response to the one-sound stimulus (e.g., tuned tone) from that to the multiple-sound stimulus (e.g., mistuned tone). ORN peaks between 140 and 180 ms from sound onset, with

Auditory Event-Related Potentials, Fig. 2 Object Related Negativity (ORN) (a) Complex tones with the second of five harmonics tuned (green) or mistuned upwards by 8% (red) were presented equiprobably in a sequence. (b) Group-averaged ($N = 20$, left; $N = 23$, right) AERP responses elicited by tuned and mistuned complex tones recorded at the vertex, separately in the passive (participants disregarded the sounds) and the active

condition (participants judged whether they heard one or two concurrent tones). Mistuned-minus-tuned difference waveforms (black) show a negative waveform appearing between 100 and 200 ms from sound onset in both task conditions. This is the ORN response (the range is marked by grey shading). The positive difference waveform observed in the 300–500 ms latency range in the Active Condition is termed the P400

the largest amplitude over the fronto-central region of the scalp (Fig. 2, panel B *left*). ORN has bilateral neural generators in auditory cortex, which are separate from those of the previously described obligatory AERP responses (Arnott et al. 2001). Some studies have indicated the existence of two independent lateralized generator processes, since although ORN is elicited even when most tones in the sequence have been mistuned, the probability of mistuned sounds within the sequence differentially affected the ORN generators in the two hemispheres (Bendixen et al. 2010). If the listener is instructed to respond when he/she hears two concurrent sounds, a late positive response (P400) is elicited in addition to the ORN (Fig. 2, panel B *right*; Alain et al. 2001).

The auditory N2 (N200; Fig. 1) wave covers at least three (N2a or MMN, N2b, N2c; see Pritchard et al. 1991), possibly more AERP components (Folstein and Van Petten 2008) appearing partly overlapping in time between 150 and 300 ms from the eliciting event. The somewhat earlier N2a or MMN does not require attention to be focused on the event (cf. MMN), whereas the later components are related to attentive monitoring of the acoustic input and they are not specific to sounds.

The *Mismatch Negativity* (MMN, N2a) is an AERP component elicited by violations of auditory regularities (Winkler 2007; Näätänen et al. 2011; Fig. 3). MMN typically emerges between 100 and 200 ms from the onset of deviation with frontocentrally dominant negative polarity that is inverted over the Sylvian fissure. MMN generators are located bilaterally in secondary-auditory and frontal areas (Alho 1995). Although traditionally regarded as a component reflecting auditory change detection, technically, MMN does not reflect acoustic change, as for example, an alternating sequence of sounds does not elicit the MMN, whereas repeating a sound within such a sequence does (Horváth et al. 2001). MMN is derived by subtracting from the response elicited by the regularity-violating sound (termed “deviant”) the response elicited by a control sound. Optimally, the control sound is either identical or very similar to the deviant sound but does not violate any auditory regularity (for a detailed discussion of selecting the correct control, see Kujala

et al. 2007). MMN is elicited even when the sounds are task-irrelevant, although it can be suppressed by strongly focusing attention on a parallel auditory channel and/or by contextual information (Sussman 2007). Initially discovered within the oddball paradigm (Näätänen et al. 1978), MMN has since been observed for violations of a large variety of abstract and complex regularities (Näätänen et al. 2001). In parallel, its interpretation shifted from MMN being an AERP correlate of auditory sensory memory (Näätänen and Winkler 1999; Cowan 1984) tasked with detecting potentially relevant events in the auditory environment (Näätänen 1992) towards the compatible but more general notion of representing a process that updates the detected auditory regularities when their predictions are not met by the incoming sound (Winkler 2007). The latter interpretation links MMN with predictive coding theories (Friston 2005; Winkler and Czigler 2012) and posits that it plays a role in auditory stream segregation (cf. ► “Auditory Perceptual Organization”) by maintaining the predictive models underlying auditory perceptual objects (Winkler et al. 2009).

The *Repetition Positivity* (RP) appears as a fronto-central amplitude modulation of the P50, N1 and P2 AERP responses (Fig. 4); all three of them overlap the slow positive RP waveform so that the P50 and P2 become more positive and the N1 less negative with increasing number of repetitions of the eliciting sound (Haenschel et al. 2005; Costa-Faidella et al. 2011a, b). Similar stimulus repetition effects have been observed even at shorter latencies, during the MLR latency range (Dyson et al. 2005). The RP was first observed by Baldeweg et al. (2004) and characterized by Haenschel et al. (2005) in a study that aimed at investigating the neural correlates of the sensory memory trace implicated in the generation of the MMN. It was argued that the MMN amplitude dependence on the number of standard-stimulus repetitions preceding the deviant (e.g., Sams et al. 1983; Javitt et al. 1998) provides only an indirect measure of the strength of the underlying memory trace. The AERP elicited by the standard sound was expected to show effects of repetition suppression (Desimone 1996), as was

Auditory Event-Related Potentials, Fig. 3 The Mismatch Negativity (*MMN*). (a) The experimental setup. Participants watched and listened to a movie presented on a TV screen directly in front of them. A series of footsteps perceived as moving from left to right (Test Sequence; *upper arrow*) or right to left (Control Sequence; *lower arrow*) were delivered by a pair of loudspeakers placed symmetrically on two sides, slightly behind the participant's head. Ten out of the 11 different digitized natural footstep sounds (marked as *black footprints* on the *blue arrows*) could be perceived as a coherent sequence produced by someone walking across a room. The tenth footstep of the Test Sequence ("deviant") and the second footstep of the Control Sequence ("control") however sounded as if the person stepped on a different surface (marked by the *white footprint* on the *blue arrows*). Street noise was delivered through a loudspeaker placed directly behind the participant. (b) Group-averaged ($N = 8$) AERP responses elicited by the deviant (*continuous grey line*) and the identical control sound (*dashed grey line*) measured

from the frontal midline electrode. The MMN component, derived by subtracting the control response from that to the deviant (difference: *black line*) is marked with *yellow-orange* fill in the MMN latency range. The results illustrate that (1) *MMN* is only elicited when a sound violates a detected regularity, as the regular progression of footsteps needed to be detected and represented by the brain before it could be violated (which could not happen if only one "regular" footstep sound preceded the different one); (2) regularities can be extracted from acoustic variance as all regular footstep sounds were acoustically different; (3) regularities are separately maintained for concurrent auditory streams, as *MMN* was elicited for deviation in the footstep stream despite the presence of two other active sound sources; and (4) *MMN* elicitation does not require one to attend the stream in which a regularity has been violated, as participants in this experiment attended the movie, not the footsteps. (Adapted from Winkler et al. 2003)

observed for individual neurons in the primary auditory cortex of the cat (Ulanovsky et al. 2003), and this could provide a more direct

measure of the strength of standard-stimulus memory trace. The typical paradigm use for obtaining the RP is called the "roving-standard"

Auditory Event-Related Potentials, Fig. 4 The Repetition Positivity (RP). *Left:* Group-averaged ($N = 14$) frontal midline (marked on the schematic head drawing at the top right corner) AERPs elicited by pure tones in a roving-standard stimulus paradigm (see in the text). The panel shows AERPs (averaged across different frequencies) elicited for the 3rd (blue), 6th (red) and 12th (green) repetition of the same tone. Note that the positivity covering the latency range of the P50-N1-P2 waveform complex emerges at the sixth repetition and becomes more

pronounced by the 12th repetition. *Right:* Difference waveforms resulting from subtracting the response to the third repetition from that to the 12th repetition under two conditions: Predictable Timing (PT: isochronous presentation, blue) and Unpredictable Timing (UT: the within-train inter-onset interval was varied, red). Note that the onset of RP is earlier (ca. 70 ms post-stimulus) for the predictable than for the unpredictable timing condition (ca. 170 ms). (Adapted from Costa-Faidella et al. 2011a)

paradigm (introduced by Cowan et al. 1993), as the classical oddball paradigm yields less clear results (Cooper et al. 2013). In the roving-standard paradigm, short trains of a repeating sound are delivered without a break with each train delivering a different sound (e.g., pure tones with different frequencies). The number of sound repetitions can also vary from train to train. To separate the RP from other concurrent AERP components, the average response elicited by the second or the third of the train is subtracted from that elicited by the last tone of the train. The response to the first sound of the train is not used in the subtraction, because, due to the sound change between the trains, it should elicit the MMN (Haenschel et al. 2005; Costa-Faidella et al. 2011a, b). The generator structure of the RP has not yet been fully characterized, but its early onset latency (commencing during the P50) and its long duration (ending during the P2) suggest that it may involve a distributed cortical network spanning from PAC up to auditory association areas (Baldeweg 2007). The RP has been shown to simultaneously encode repetitions

over multiple time scales (Costa-Faidella et al. 2011b; Cooper et al. 2013) similarly to single neurons observed in the cat's PAC (Ulanovsky et al. 2004). In addition to stimulus repetition, the RP is also sensitive to temporal regularities, such as whether the sounds are presented isochronously or with random timing: Costa-Faidella et al. (2011a) found earlier and larger RP's for isochronous as compared with randomly timed tones in the trains. The latter result supports the predictive coding view of auditory deviance detection (Winkler 2007; Winkler and Czigler 2012), according to which detection of a regularity helps to encode the sensory memory trace of upcoming stimuli. Thus higher levels in the auditory processing hierarchy feed back to lower processing levels (Baldeweg 2006).

Auditory brain responses can also be elicited without hearing sounds. By omitting sounds from an isochronous sequence, one can record potentials time-locked to the moment when the sequence would have continued in a regular manner. The responses are termed the *Omitted Stimulus Response (OSR)*. Some of them are elicited

even when listeners don't focus on the sounds, thus demonstrating a basic tendency of the auditory system to generate predictions for incoming sounds (Friston 2005; Winkler et al. 2009). It has been shown that when all features of the upcoming sound can be predicted from the preceding sound sequence, the OSR elicited by sound omission during the first 50 ms does not differ from the AERP elicited by the sound itself; however, when only the timing of the sound can be predicted, but not its features, the OSR starts to differ from the corresponding AERP at an earlier time (Bendixen et al. 2009). When sounds are predictably caused by some action of the listener, occasionally omitting one elicits an AERP that is initially (up to ca. 100 ms) morphologically similar to that elicited by the corresponding self-initiated sound; although the brain generators underlying the two responses partly differ from each other (SanMiguel et al. 2013). There is also an MMN-like OSR (Yabe et al. 1999). Elicitation of these responses is limited to inter-onset-intervals (IOI) shorter than ca. 200 ms (Horváth et al. 2007), except when the omitted sound is part of a pattern (Salisbury 2012). With longer IOIs, an early posterior negative (180–280 ms) response and a later anterior positive wave have been obtained (Busse and Woldorff 2003). Further, ERP responses can also be elicited by mental imagery of sounds, although the results vary somewhat with the procedure employed (Meyer et al. 2007; Cebrian and Janata 2010; Wu et al. 2011).

Attention-Related AERP Responses

Attention-related AERPs include two distinct groups of responses: those related to involuntary (passive or exogenous) attention, and those related to voluntary, mainly selective attention. Regarding involuntary attention, at least three components have to be considered. The MMN (described above), or at least its frontal component (Giard et al. 1990; Deouell et al. 1998; Escera et al. 2000a; Deouell 2007), has been associated with involuntary attention (Näätänen and Michie 1979; Näätänen 1990, 1992). Some studies have also related the activation of the supratemporal MMN generator with behavioural correlates of

involuntary attention, i.e., delayed response times to target stimuli on a primary task (Yago et al. 2001). Näätänen and Michie (1979) proposed that the process generating MMN may issue a call for focal attention (Öhman 1979) upon the detection of an unexpected change in the acoustic environment. Initial supportive evidence was provided by Schröger (1996; Schröger and Wolff 1998a) and Escera et al. (1998), who introduced new auditory-auditory and auditory-visual distraction paradigms (for a more recent design, see Horváth and Winkler 2010). In these paradigms, participants are instructed to perform a primary auditory or visual task while ignoring rare task-irrelevant violations of an auditory regularity. Several studies have shown that these rare deviations prolong the reaction time and reduce the hit rate to target stimuli in the primary task (Escera and Corral 2007), thus demonstrating involuntary attention switching to the task-irrelevant deviations.

Following the MMN, AERPs recorded in the distraction paradigm display a fronto-central positive deflection ca. 250–350 ms from stimulus onset, termed the *P3a* or *novelty-P3*. *P3a* was first described by Squires et al. (1975) as an earlier and more frontal positive deflection compared to the later and more posterior *P3b* component (for a review on *P3b*, see Donchin and Coles 1988). Whereas *P3a* is elicited by rare task-irrelevant sounds, *P3b* is elicited by target sounds (for a detailed comparison between the *P3a* and *P3b*, see Polich 2007). *P3a* is also elicited by widely different and “novel” (unique, categorically different from the context) sounds (Knight 1984), hence it is sometimes referred to as the *novelty-P3* (for a discussion of whether the *P3a* and the *novelty-P3* can be considered as the same ERP component, see Simons et al. 2001). Compelling evidence linking the *novelty-P3* to the orienting reflex (OR; Sokolov 1963) was obtained by Knight (1996), who found strong correlation between the *novelty-P3* and one of the well-known autonomic components of OR, the galvanic skin response (GSR). The *P3a* is composed of two subcomponents distinctly differing in latency (early and late), scalp distribution, and

sensitivity to attentional manipulations (Escera et al. 2000a; Yago et al. 2003). Source modelling of the magnetic counterpart of P3a (P3am) elicited by auditory deviants and novel sounds has revealed a genuine auditory cortical contribution to the early part of P3a (Alho et al. 1998). Whereas the early part of the novelty-P3 appears to be insensitive to attentional manipulations (Escera et al. 1998), the later part is modulated by working memory (SanMiguel et al. 2008) and emotional load (Domínguez-Borràs et al. 2008). The early P3a is sensitive to stimulus-specific information predicting task-irrelevant auditory deviance, whereas the late P3a appears to be more closely correlated with distraction (Horváth et al. 2011). P3a is widely regarded as a correlate of attention switching (Escera et al. 2000a; Friedman et al. 2001). However, some recent studies suggested that although P3a is probably an antecedent of attention switching it can be elicited without a corresponding shift in the focus of attention (Rinne et al. 2006; Horváth et al. 2008b; Horváth and Winkler 2010; Hölig and Berti 2010).

The third involuntary attention related AERP component is the so-called *Reorienting Negativity* (RON), first described by Schröger and Wolff (1998b). RON is observed as a negative deflection following the P3a (Escera and Corral 2007). RON has been suggested to reflect processes of reorientation (restoring the task set of the primary task) after a distracting stimulus. RON is composed of two subcomponents (Escera et al. 2001; Munka and Berti 2006; Berti 2008) the functional characterization of which are still debated (Escera et al. 2001; Berti 2008). The cortical generators of RON are not well known. Horváth et al. (2008a) found contributions from primary motor areas to RON, suggesting that action-selection related activity plays a role in the reorientation process. Both P3a and RON as well as behavioural correlates of distraction (but not MMN) are eliminated or at least strongly diminished when the task-irrelevant deviant is predicted by a visual cue (Sussman et al. 2003; Horváth and Bendixen 2012). Cues that provide more specific information about the distracting stimulus are more effective in preventing

distraction and the elicitation of P3a and RON (Horváth et al. 2011).

Selective attention related AERPs have been traditionally studied in the context of the classical “cocktail-party” situation described by Cherry (1953). In the simplified dichotic listening model of this situation, participants are exposed to two concurrent messages (one to each ear). Using this paradigm, many studies attempted to decide between the “early” (Treisman 1964; Treisman 1998; Broadbent 1970) versus “late” selection theories of attention (Deutsch and Deutsch 1963; Norman 1968). These theories of attention primarily differ from each other in the placement of a selective filter within the chain of information processing (Broadbent 1958): whereas early selection theories suggest that stimuli are selected for elaborate processing based on simple sensory features (such as pitch) and unattended stimuli do not receive processing beyond extracting these sensory features, late selection theories propose that all stimuli receive elaborate processing and stimuli can therefore be selected on the basis of higher-order properties. (Note that more recent theories of attention do not posit a single selective filter; see e.g., Lavie 1995.) The seminal observation by Hillyard et al. (1973) that selective attention enhances the N1 amplitude for stimuli presented in the to-be-attended channel favoured the early filtering view. However, the findings of Näätänen et al. (1978) of a long-lasting negativity elicited by all attended stimuli, the *Processing Negativity* (PN; Näätänen 1982) challenged this interpretation providing support to late-selection theories. Subsequent studies confirmed both of these effects (Okita 1979; Hansen and Hillyard 1980; Näätänen et al. 1980) and proposed subtraction of the AERP elicited by the non-attended stimuli from that elicited by the attended stimuli as the method to reveal the *Negative Difference* (N_d) potential to isolate the AERP correlates of selective attention (N_d ; Hansen and Hillyard 1980). The N_d is composed of two parts: the early one, termed N_{de} , associated with a gating mechanism preferentially processing the task-relevant stimulus features, and a later part (N_{dl}) related to the maintenance of the attentional trace (correspond to the PN). The functional distinction

between the Nd and PN has been debated in detail (Alho et al. 1986a; Alho et al. 1986b; Alho et al. 1994; Teder et al. 1993). Studies showing very early selective attention effects, e.g., at the latency range of the MLR (Woldorff et al. 1987; Woldorff and Hillyard 1991) and possibly even earlier, at the level of the cochlea (Giard et al. 1994) support the interpretation of the Nd_e as a correlate of gating by simple stimulus features. On the other hand, the fact, that the more similar the stimulus to the target the longer the corresponding PN, supports the notion of a comparison with the attentional trace. The frontal scalp distribution of Nd_i (Woods and Clayworth 1987) and the cerebral sources of PN (Giard et al. 1988) are also compatible with the memory-based interpretation of Nd_i. There are several further ERP components related to various facets of attention. However, these are not specific to the auditory modality and thus fall outside the scope of this entry.

AERPs Reflecting Speech and Music processing

The sounds of speech and music may elicit any and all the AERP responses described above. There are, however, also some ERP responses, which arise from events that can be defined in syntactic or semantic terms. It should be noted that most speech-related ERPs can also be elicited through reading. Most AERP responses specific to speech and music have been obtained in paradigms, in which the expectation for the most likely (or simplest) continuation of a sequence of words has been violated. For example, violating the expectation for the first phoneme of the upcoming word elicits a negative shift in the 150–350 ms latency range, termed the *Phonological Mismatch Negativity* (PMN; Connolly and Phillips 1994). It is, however, debated, whether this response can be separated from that elicited by words, which are semantically incongruent with respect to the preceding context (D'Arcy et al. 2004; Van den Brink and Hagoort 2004). Violating speech syntax can lead to the elicitation of the *Early Left Anterior Negativity* (ELAN) in the 150–200 or the *Left Anterior Negativity* (LAN) in the 300–500 ms latency range, depending on the type of violation, whereas potentially correct

but syntactically complex sentences elicit the *Syntactic Positive Shift* (SPS or P600) (for reviews, see Friederici 2002; Hagoort 2008). Violating semantic expectations in speech elicits the N400 component (Kutas and Federmeier 2011). Musical syntax violations elicit an ELAN-like but predominantly right-hemispheric response, the *Early Right Anterior Negativity* (ERAN) in the 180–200 ms or the *Right Anterior-Temporal Negativity* (RATN) in the 200–400 ms latency range and N400 has been also observed in musical models of semantic incongruence (Koelsch and Siebel 2005). For a more detailed discussion of speech- and music-related ERPs, see ► “Electrophysiological Indices of Speech Processing” and ► “Music Processing in the Brain”.

Development of AERPs

Previous sections described the AERP responses elicited in adults. Although AERPs can be recorded immediately after birth and even in fetuses within the womb (Draganova et al. 2005), their morphology and functional characteristics widely differ from the adult responses. Further, different AERP components become mature at different times and they often undergo several intermediate phases before reaching adult-like characteristics. As this topic would require a full entry of its own, here we point the reader to some of the existing literature. The most complete reviews of the maturation of AERPs from infancy to adolescence were provided by Wunderlich et al. (2006) and Coch and Gullick (2012). The early infantile development of the AERP components has been summarized by Kushnerenko (2003); for the maturation of the AERPs reflecting auditory change detection, see Jing and Benasich (2006), for large deviations, see Kushnerenko et al. (2013). The maturation of obligatory AERP components from 5 to 20 years of age is covered in Ponton et al. (2000, 2002). AERP maturation during adolescence is described in Bishop et al. (2007). Summarizing these works, one can conclude that the adult AERP morphology characterizes humans from 17/18 years onward and remains more or less unchanged through ageing. There are, however several findings of differences between elderly

and young adults in specific tasks (for a review, see Friedman 2012).

Modelling AERP's: Some General Principles

Theories that seek to explain some of the LLRs have also been explored using more tightly constrained mathematical and computational models. Here we focus on models of the mismatch negativity (MMN) component, as it has arguably received the most widespread attention. Theoretically, MMN has been variously associated with change detection, adaptation, prediction error, novelty detection, and model adjustment, although for some years, there has been controversy as to whether anything more than adaptation is required to explain the experimental data (e.g., see May and Tiitinen 2010 vs. Näätänen et al. 2011).

Using a modelling framework in which exemplars of each of the competing explanations, listed above, were expressed as mathematical functions of stimulation-induced changes in an *unobservable* 'internal state' and resulting *observable* (EEG) responses, Lieder et al. (2013) investigated the ability of each model to explain empirical MMN responses on a trial-by-trial basis. The models were expressed in a rather abstract way, as summarized below, with simple expressions for internal state and response functions (intended to predict stimulus-evoked MMN amplitudes), that captured a range of possibilities for each of the categories. Change detection was modelled with the internal state simply a record of the log frequency of the previous tone in the sequence, and response functions as: a) a flag, set if a difference was detected, b) the signed and c) absolute difference between the frequency of the incoming and previous tone; giving three change detection models. Adaptation was modelled by the exponential decay and recovery of the internal state variable associated with each stimulus frequency, and the response function as a read out of the internal state corresponding to the incoming stimulus. The internal state for the prediction error, novelty detection, and model adjustment accounts was modelled as a Bayesian observer's belief in the tone category of the stimulus, with the evolution of tone category modelled

according to a transition matrix derived incrementally from the data according to the 'free-energy-minimisation principle' (Friston 2005). Two prediction error response functions were modelled: prediction errors with respect to sensory input and internal state, respectively. Novelty response functions were modelled as surprise about sensory input and temporal structure (tone category), respectively. Model adjustment response functions were modelled in terms of adjustments to the parameters of the internal model, e.g. mean frequency of a category, expected sequence length, transition probabilities between categories. Simulations showed that, at least at this level of detail, prediction error (with respect to tone category) and model adjustment models (change in expected sequence length, change in transition probabilities between categories), accounted best for the data (Lieder et al. 2013).

On the other hand, May and Tiitinen (2010) have argued strongly that their neural model which includes adaptation on the inputs can explain all MMN data to date; the key mechanism being the activation of fresh afferents by stimuli that deviate in some way from the standards. In this account, MMN is seen as a modulation of the N1 component rather than as a separate component in its own right. The model, consisting of a bank of neural oscillators driven via adapting input synapses, can account for the latency as well as the amplitude of the MMN (May et al. 1999). In addition, extending the model to include local inhibitory feedback circuits, results in a set of non-homogeneous band-pass temporal filters that can also support the topographic representation of stimulus presentation rate (May and Tiitinen 2001). Ringing in these filters is argued to account for the MMN elicited by a missing expected sound. Diverse receptive fields, e.g. to frequency modulations, also allow the model to simulate MMN responses elicited by violations of some abstract rules, such as a repeated tone in a random pattern of ascending tone pairs. However, although adaptation is claimed to be the key to MMN, the model responses also depend upon the amplification of recurrent excitation, lateral inhibition, and the connectivity of the network. The

model thus essentially contains within its changing pattern of adaptation and inhibition, a memory trace of recent activation, and in this sense, contains a memory component embedded within it.

Building on their previous work on a brain-inspired architecture for learning long-term representations of action-perception associations, Garagnani and Pulvermüller (2011) proposed a similar model in which, in addition to adaptation and inhibition, spreading activation through circuits strengthened by learning (long term memory) caused MMN responses to familiar deviants to be larger than that to unfamiliar deviants. They pointed out that only through some form of long term memory mechanism could this differential sensitivity of MMN to familiarity/unfamiliarity be explained. By modelling multiple auditory areas they also provided a novel explanation for differences between the N1 and MMN generators, with N1 being generated in primary auditory areas subject to strong adaptation, and MMN in addition to adaptation also being influenced by reverberating excitation within distributed memory circuits. However, the model processes sequences of static patterns, and as presented, it is not able to account for the sensitivity of MMN to unexpected changes in the timing of sequences, such as the omission MMN (Yabe et al. 1997).

A model that explicitly includes a separate memory module to keep track of the short term history of activation and simulates MMN at a finer level of granularity, i.e. at the level of spiking neurons, was proposed by Wacongne et al. (2012). Memory in the model is implemented using a set of neurons organised into a delay line, i.e. their connectivity ensures that activity passes in one direction across the population, and the progress of activity through this population explicitly represents the timing of the previous event, up to 400 ms. Separate delay lines are used for each tone frequency modelled, thereby also recording their identity. The model simulates MMN by means of prediction errors. Through exposure to tone sequences it learns to generate a prediction of the next tone (both its timing and identity) in a repeating pattern. These predictions are compared with the incoming stimuli in the prediction error units, where mismatches result

in a larger signal than matches. The model learns transition probabilities between successive events, as long as they fit within its fixed memory span. In contrast to the adaptation account of MMN, the model relies exclusively on prediction errors. An experiment designed to distinguish between these two explanations for MMN found evidence in favour of a predictive error model of MMN (Wacongne et al. 2012), a result compatible with the findings of Lieder et al. (2013).

A predictive coding account of MMN has also been modelled at a more abstract level using a Kalman filtering (Kalman 1960) approach (Kaya and Elhilali 2013). In this case the timing of events is modelled using a separate filter from the one used to model feature distributions. The advantage of the Kalman filter is that it provides a well-understood way to recursively estimate the system state, refined through analysis of prediction errors, and has been shown to be implementable in the form of a neural network (Szirtes et al. 2005). The model adapts to the variance in observations and, with time, as its predictions improve so its tolerance decreases, making it more sensitive to outliers. Deviants are detected as events not predicted by any existing filter, and trigger the creation of a new set of Kalman filters intended to model a potentially new sound source, making this an interesting framework for more general auditory scene analysis problems, e.g. (Chakrabarty and Elhilali 2013).

In summary, computational models of the theoretical accounts of MMN have begun to be explored. However, so far they have either only been implemented at a rather abstract level; e.g. (Garrido et al. 2009; Lieder et al. 2013; Kaya and Elhilali 2013), focus exclusively on a single mechanism for explaining MMN; e.g. (May and Tiitinen 2001; Wacongne et al. 2012) or account only for MMN responses to unexpected within-event properties (Garagnani and Pulvermüller 2011; Garagnani et al. 2008). The finding, using dynamic causal modelling, that modifications to both feed forward and feedback connections are required (Garrido et al. 2009), and evidence in auditory cortex for adaptation, short term and long term plasticity, recurrent excitation

and inhibition suggests that MMN in the brain may actually depend on the combination of all these factors. Furthermore, while the learning of transition probabilities may be sufficient for some scenarios, in the short term at least, people become sensitive to specific tone patterns; it is unclear whether any of the models discussed here could respond differentially to violations of more extended pattern sequences or more abstract rules.

Utility of AERP for Clinical Practice

Clinical applications of AERPs range from routine practice in audiology, neurotology, neurology, and neurosurgery by ABRs and MLRs (Picton 2010) to highly promising tools for cognitive assessment by some long-latency endogenous components, of which MMN is a prime example. In audiology, ABRs are used universally for hearing screening in neonates failing the Otoacoustic Emission test (OAEs; Robinette and Glatcke 2007). Currently, about 97% of infants are screened for hearing impairment in the USA (Gaffney et al. 2010). ABRs, elicited by click stimuli, are used as a tool for objective audiometry, and ABRs elicited by pure tones can also be used for assessing frequency-specific thresholds in infants (Stapells and Oates 1997; Stapells et al. 1993). In neurotology and neurology, AERPs are combined with the patient's medical history and with an extensive battery of tests for evaluating the anatomy and functional properties of the ear-brain relationship (Picton 2010) in search for an extensive range of disorders of the ear and the auditory pathway, such as Ménière's disease and demyelinating lesions such as Multiple Sclerosis. In these applications, AERPs are used to determine conduction times along the auditory pathway and to localize the anatomical locus of the brain damage with the help of the known origin of the different ABR waveforms (see reviews in Baloh 1997; Chiappa 1997; Lustig et al. 2003). In addition, ABRs are used in combination with evoked potentials from other modalities to monitor coma prognosis (Guérit 2005; Fischer et al. 2006; see below), or in isolation to corroborate brain death (Machado et al. 1991). In the surgical theatre, MLR is used to monitor the depth of

anaesthesia in adults (Bell et al. 2004) and children (Kuhnle et al. 2013). It has been recently shown that, compared with the traditional clinical assessment of depth of anaesthesia, MLR monitoring led to a reduction in (a) the amount anaesthetic drug requirement, (b) the use of vasopressors to manage hypotension, and (c) consequential cognitive impairment (Jildenstål et al. 2011).

Regarding cognitive AEPRs, MMN (see above) has shown great promise for potential clinical applications (Näätänen and Escera 2000). Part of this expectation stems from the fact that MMN indexes auditory discrimination accuracy without the requirement to perform some task (i.e., it can be recorded without the patient's collaboration and even in newborn infants; see Alho et al. 1990) and that it can be elicited very reliably, compared with other cognitive event-related potentials (Escera and Grau 1996; Escera et al. 2000b). Yet, after two decades of clinical research (see Näätänen et al. 2012), except for coma monitoring and prognosis no routine clinical application has emerged for the MMN. As for coma monitoring, it has been demonstrated that the presence of MMN in a comatose patient is associated with the return of consciousness (Kane et al. 1993; Fischer et al. 1999), and that as part of a battery of physiological indicators of brain activity, MMN can be used in the decision tree for estimating awakening from coma (Fischer et al. 2006). Given the large variety of disorders and clinical conditions in which impaired MMNs have been observed, it has been suggested that, rather than providing a specific diagnostic measure for any particular disease, the MMN provides an objective index of dysfunction of *N*-methyl-D-aspartate (NMDA) receptor-mediated cognitive functions (Näätänen et al. 2011). In general, due to their high variability and complex functional and anatomical origin, endogenous AERPs can only be employed within large test batteries for diagnostic and monitoring purposes. However, some of these responses provided new insights into the cognitive and emotional aspects of various neurological and psychiatric disorders (e.g., for schizophrenia research using MMN, see Mondragón-Maya et al. 2011).

AERPs: Advantages and Limitations

(A)ERPs provide information about sound-elicited neural activity with millisecond accuracy. Thus they are ideally suited for breaking down the steps of auditory information processing in the brain in the empiricist tradition. It is thus understandable that some of the most recent theoretical developments in the field (e.g., predictive coding theories; Friston 2005) trace back their roots to Helmholtz' (1860/1962) theories of perception. High temporal resolution coupled with the possibility of finding the neural generators of the various ERP responses is also appealing to neurologists and medical doctors, in general. By finding correlations between AERPs and conscious perception on the one hand (such as the link between ORN and the perception of two concurrent sounds; Alain et al. 2001), and discovering the neural mechanisms underlying the observed AERP waveforms on the other hand (e.g., linking SSA and the deviance-detection responses observed in the MLR latency range; Slabu et al. 2010; Grimm et al. 2011; for a review, see Ayala and Malmierca 2013), AERPs can provide a crucial link in understanding the neural mechanisms of perception.

However, there are a number of limitations to the utility of (A)ERPs for research and applications. Firstly, they only reflect a part of the information processing in the brain. When the number of neurons involved in some process is relatively small, or the neurons are distributed over a large area in the brain, or the neural activation is not fully time-locked to the given auditory event, no ERP can be measured. Other methods, such as time-frequency analysis of the EEG, provide better information about these types of processes. AERPs are usually smaller than their visual counterparts. Consequently the signal to noise ratio, where activity not time-locked to the sound onset is regarded as noise, is quite low. This forces one to present many trials to the participant and rely on assumptions which are not fully met by the EEG signal (such as the independence of the signal from the noise, ergodicity, etc.). Further, the accuracy of localizing the sources of neuroelectric activity is limited by the quality of constraints (e.g., anatomical knowledge) required to solve

the inverse problem, and the dispersion of the electrical fields. Although magnetoencephalography provides a better spatial resolution, as was already mentioned, AEFs only reflect tangential sources, but not radial ones, thus restricting their general usefulness. In terms of spatial accuracy, other neuroimaging methods, such as fMRI, provide a superior alternative (at the cost of much lower temporal resolution). Further, the correspondence between perception and AERP responses is often not straightforward, as can be gleaned from the often controversial psychological interpretations mentioned in the main text of this entry. Few AERP components can be consistently observed across different stimulus paradigms, thus limiting the validity of most process-based interpretations. Efforts to discover the neural bases of ERP responses must overcome many obstacles. One of the most difficult problems is that whereas individual neurons can mainly be studied in animal models due to the invasive nature of such investigations, it is often difficult to assess how well findings in various species can be extended to characterizing the human brain. Finally, the biggest issue for clinical applications is, as was already mentioned, the large inter- and even intra-individual variability of AERPs.

In summary, AERPs can potentially provide much information about sound processing in the brain, but for extracting this information, better theories and more tightly constrained models, which can integrate information from the diverse fields of anatomy, neuroscience, and psychology, are required.

Definition

The frequency-following response (FFR) is a sustained auditory evoked potential that reflects synchronous neural phase-locking to the spectrotemporal components of the acoustic signal. FFRs are recorded noninvasively from the scalp with electroencephalography (EEG) and with magnetoencephalography (MEG) and emerge at circa 7–15 ms from sound onset to auditory frequencies in the range 100–1500 Hz. By reflecting phase-locked activity to the incoming sounds, FFRs faithfully mimic and are as complex as the eliciting stimulus as it unfolds in time, so that they can be recognized as such when played through a speaker. The FFR has gained recent interest in auditory cognitive neuroscience as it captures with great fidelity the tracking accuracy of the periodic sound features in the ascending auditory system. By decomposing the FFR in the temporal and spectral domains, it is possible to read neural traces from the scalp as sounds are transcribed in neuronal aggregates and

how these neural sound traces are shaped by experience, context, and challenging conditions, such as listening in noise, with age and in speech and language disorders.

Detailed Description

Introduction to the FFR

The auditory system is essential for us humans, as it allows to make sense of the sounds around us and to decipher the complex spectrotemporal signals hidden in the ongoing acoustic flow, hence supporting human communication, building our cognitive system through the use of language, and promoting social interaction through the joy of music. Acoustic signals are transduced into a neural code in the inner ear and then released through the auditory nerve to the central nervous system. Understanding how the central auditory system encodes for the different spectrotemporal attributes of sounds and isolates different auditory objects is thus capital to understand the way we use sounds to communicate and interact with others, and the frequency-following response provides a valuable neurophysiological tool to unravel these mysteries. The FFR was originally recorded in animal preparations of the auditory nerve and ascending fibers of the auditory pathway as synchronous phase-locked activity in neuronal aggregates elicited to pure tone stimuli. In humans, it was first recorded by Moushegian, Rupert, and Stillman in 1973 (Moushegian et al. 1973) to pure tone stimuli of frequencies of 0.25, 0.5, 1.0, 1.5, and 2.0 kHz, as they could show compelling evidence of the neuroelectric recordings to follow the cycles of the eliciting stimuli at these different frequencies, and of these neuroelectric signals being of central nervous origin.

The FFR is currently conceived to reflect an aggregation of phase-locked neural activity from multiple generators along the auditory system, although it has been considered for long as a putative measure of subcortical sound encoding. The FFR can be obtained under passive and active listening paradigms, and it is highly sensitive to context-dependent contingencies and to real-time

statistical properties of the incoming stimulation (Escera 2017). It is also modulated by short-term auditory training and lifelong auditory experience, including musical training and linguistic competence. Consequently, the FFR has become a major tool in the assessment of the neural encoding of speech sounds in both healthy and clinical populations (Kraus et al. 2017). By means of a range of analytical tools in the temporal and spectral domains, the FFR provides an objective indicator of the fundamental acoustic features intrinsic to speech sounds, including timing (onsets), pitch (fundamental frequency, F0), and timbre (the harmonics information). Specifically, it informs about the latency and amplitude of the auditory input in the time domain and the magnitude of the fundamental frequency and its harmonics in the frequency domain (Kraus et al. 2017) (Fig. 1).

While the term frequency-following response is the most broadly used and probably the most comprehensive one, there are other terms that have been used interchangeably or which highlight a specific aspect or variant in the response. These include *complex auditory brainstem response* (cABR), *speech auditory brainstem response* (sABR), *envelope-following response* (EFR), and *amplitude-modulation following response* (AMFR). As seen, some of these variants refer to the auditory brainstem response (ABR) for good technical reasons: FFRs are recorded with the same equipment and settings as the ABR. In fact, the ABRs can be decomposed into two distinct components, the transient-evoked responses and the FFR (see entry ► “Auditory Brainstem Responses”). In addition, as introduced above and explained in further detail below in this entry, the use of the term “brainstem” in naming this auditory evoked potential conveys an anatomical implication that has been overcome by the available evidence. Indeed, FFR was considered since seminal studies to have a primary origin in the inferior colliculus of the auditory midbrain, yet recent studies have indicated that the FFR represents an integrated response of the entire auditory system, with contributions from both subcortical but also cortical centers. Therefore, including anatomical indications on the terminology can lead to

misconception. Overall, the scientific community has agreed to the term FFR being the most appropriate one, as it only refers to what the component is: a response that follows the frequency of the incoming stimulus (Kraus et al. 2017).

Importantly, the FFR has a great potential to inform basic and applied questions in learning and communication. Throughout this entry we will review the technical considerations for recording the FFR and computing a large range of FFR-derived measures. We will also discuss its neural origins and how it develops throughout the individual’s life-span. Finally, we will characterize the FFR by showing its sensitivity to different auditory contexts and experiences and its role in the study of clinical conditions.

Recording the FFR: Technical Considerations

Selecting appropriate stimuli to elicit reliable FFRs depends on several factors, including specific research purposes as well as taking into account the properties of the electrophysiological response per se. Some of the most commonly used stimuli include *pure tones* (i.e., simple sinusoids), which allow the assessment of responses phase-locked to the sound waveform (response peaks appear with the same periodicity than in the eliciting stimulus); *amplitude-modulated tones*, enabling the study of responses to the amplitude envelope; *complex tones*, used to study both the encoding of different spectral components and the periodic aspects of the sound; *synthetic vowels* and *natural vowels*, used to study the encoding of vowel formant structure with linguistic material; *consonant-vowel syllables*, possibly the best studied, allowing to reveal the encoding of fast formant transitions and sustained responses to vowels (e.g., /da/ vs. /ga/) as well as meaningful pitch contours in tonal languages (slower changes in sound periodicity, e.g., in Mandarin lexical tones); *musical sounds* from different musical instruments, used to study the encoding of harmonic structure and other timbre characteristics; and even *iterated rippled noises*, which are noise stimuli with periodic structure that can be used to study the emergence of perceptual pitch and its neural encoding (Chandrasekaran and Kraus 2010; Skoe and Kraus 2010a).

Auditory Frequency-Following Responses, Fig. 1 Morphology and characteristics of the human scalp-recorded FFR. The frequency-following response (FFR) can be recorded to complex auditory stimuli, such as a consonant-vowel /da/ utterance (upper panel). The middle panel shows the FFR recorded from the Fpz electrode in one single individual (human neonate) to such a stimulus. As can be appreciated, the FFR faithfully mimics the incoming stimulus by phase-locking to its temporal features; notice

the same number of cycles within the framed portion in both the stimulus and the neural response. The central origin of the FFR, as opposing to a cochlear origin, is reflected by the short delay in the emergence of phase-locked neuroelectric signal, which corresponds to the neural delay the signal needs to reach the central generating structures within the auditory pathway. In addition to phase-locking to the stimulus temporal components, the FFR also encodes for the spectral features of the incoming stimulus, as can be seen

All these stimulus types are fully periodic or contain periodic sections, and, in order to elicit robust FFRs, their fundamental frequencies (F0) usually range between 80 and 300 Hz, falling within the natural speech range. Their frequency content may span up to 10 kHz, but the FFR signal becomes weaker with increasing frequency (Greenberg 1980), and its phase-locking limits are around 1500 Hz. However, most of the spectral information needed to distinguish vowels is well below 3000 Hz. Stimuli are commonly delivered binaurally at conversational suprathreshold intensities (60–85 dB SPL) to approach naturalistic settings, although monaural stimulation can as well be used. Stimulus duration ranges from several tens of milliseconds to seconds (e.g., 40 ms to 2 s), and interstimulus intervals also vary widely, only limited by experimental time constraints, which may depend on the studied population (recording sessions are shorter in babies or patients suffering from different conditions than in young healthy adults). A common practice is to deliver half of the stimuli with opposite polarity (180° phase shift) to allow averaging and subtracting responses across polarities in order to emphasize responses to the sound envelope (useful to extract pitch tracking measures) or to the spectral content (and study vowel formant structure encoding), respectively (Aiken and Picton 2008; Skoe and Kraus 2010a). Given the small amplitude of the FFR signal (i.e., in the range of a tenth of a μV), a typical recording needs roughly 1000–2000 stimulus presentations to be averaged further per polarity (if applicable).

FFRs are typically recorded with scalp electrodes using essentially the same montage and settings than those used to record ABRs (see entry ► “Auditory Brainstem Responses”). In a characteristic montage, an active electrode is placed over the vertex of the scalp or on top of the forehead; a reference electrode is placed on an earlobe (or the mastoid or a high vertebra, at the expense of muscle noise and bone vibration), and a ground electrode is located either on the other earlobe or on the middle of the forehead (Skoe and Kraus 2010a). Impedances are usually kept below 5000 Ω . Recording sampling rate should be at least as high as the double of the highest sound frequency to be studied, although researchers usually oversample (10 or 20 kHz) in order to obtain fine temporal variations in the signal that could be informative (Skoe and Kraus 2010a).

Regarding the most common analysis methods, the FFR is generally computed as an auditory event-related potential (see entry ► “Auditory Event-Related Potentials”) by averaging or sub-averaging per polarity the total number of available trials, in windows lasting typically from –40 ms to 20 ms poststimulus ending. Importantly, the FFR can be distinguished from the cochlear microphonic, a receptor potential generated in the outer hair cells that mimics the incoming stimulus, as the FFR has a 6–10 ms delay poststimulus onset/peaks, while the cochlear microphonic is nearly coincident with the stimulus waveform, or by cancelling the latter via averaging responses to opposite stimulus polarities (Skoe and Kraus 2010a).

Due to the shared characteristics between the FFR and the sound used to elicit it, most of the

Auditory Frequency-Following Responses, Fig. 1 (continued) in the *frequency spectrum*, *pitch tracking* accuracy, and *spectrograms* computed from FFR of this very same individual (bottom panel). The *frequency spectrum* illustrates the amplitude spectral decomposition of the whole FFR, which reveals a clear peak corresponding to the stimulus fundamental frequency. *Pitch tracking* accuracy provides a measure of the ability to track changes in the fundamental frequency along the stimulus entire duration (stimulus frequency depicted in black; response tracking in red). The *spectrogram* provides combined information regarding the frequency and the amplitude at

which the FFR is phase-locked to the different spectral components of the incoming stimulus along its entire duration. The color scale from black to white indicates the spectral amplitude in μV , with lighter colors depicting highest amplitude values. Overall, this figure illustrates how the FFR faithfully tracks the eliciting stimulus and its complexity even in a single individual, thus providing a valuable tool to address issues in auditory cognitive neuroscience as well as the assessment of hearing abilities at individual level. Figure adapted and reproduced with permission from Ribas-Prats et al. (2019)

analyses and interpretation on FFRs are based on the acoustic properties of the stimulus, assessing timing and neural synchrony magnitude, as well as phase-locking strength and precision (Skoe and Kraus 2010a). The following are common parameters that are extracted from time and frequency domains, in fixed or sliding windows (to capture changes as a function of time), attempting to disentangle several auditory neural processing features that the FFR may reveal: *stimulus-to-response cross-correlation*, showing the accuracy with which the FFR replicates the stimulus waveform; *neural lag*, an estimation of the temporal delay between stimulus and response; *consistency*, a measure of neural response stability; *root mean square (RMS) amplitude*, indicating the overall magnitude of neural activity over a determined period of time; *pitch strength*, a measure of periodicity based on autocorrelation that reflects the robustness of the response's phase-locking to the stimulus F0 contour; *pitch error*, a measure of how faithfully the FFR encodes the pitch along the stimulus duration, measured as a difference in Hz from the stimulus F0 contour; *spectral amplitude*, usually computed with fast Fourier transform, indicating the magnitude of neural phase-locking at a certain frequency (F0 and harmonics); and *points below noise floor*, describing how the signal can be differentiated from baseline (i.e., pre-stimulus) noise (see Ribas-Prats et al. 2019, for an empirical implementation of all these measures).

Neural Generators

Despite the accumulation of studies on the neural origins of the FFR, no clear picture has emerged so far regarding its anatomical generators, and certain controversy is still being debated. Early seminal studies were addressed to demonstrate that the FFR had a central rather than a cochlear origin, and its sources were attributed to neuronal aggregates in caudal brainstem and midbrain structures, with the inferior colliculus (IC) being the major neuronal source. These seminal studies supported somehow the use of “brainstem” in variants of the nomenclature and its treatment as a putative correlate of subcortical sound encoding. The midbrain origin is supported by the fact that the short latency of the FFR aligns with the latency of the first spikes

in IC (Langner and Schreiner 1988) and since FFRs contain phase-locked activity up to 1500 Hz, which spans beyond the upper limit of phase-locking capabilities of cortical neurons (~100 Hz; Aiken and Picton 2008). Additionally, focal lesions (Sohmer et al. 1977) as well as the cryogenic cooling of the IC result in the abolishment of FFRs, with subsequent heating in this later case yielding recovering of FFRs both in the IC and at the scalp (Marsh et al. 1970; Smith et al. 1975). Nevertheless, a mixture of brainstem sources was indeed recognized in the generation of the FFR (Chandrasekaran and Kraus 2010; Tichko and Skoe 2017) and was further supported by other studies that reported weaker contributions of the IC to the FFR, with the major source located in the CN (Gardi et al. 1979a) or in the MGB (Weinberger et al. 1970).

Recently, the controversy around the neural origins of the FFR was renewed with MEG evidence demonstrating that the responses to a complex auditory stimulus of a fundamental frequency close to 100 Hz receive contributions not only from the subcortical nuclei (i.e., the cochlear nucleus and the IC) but also from the medial geniculate body of the thalamus and to a major extent from the auditory cortex (Coffey et al. 2016, 2017). The implications of these findings need, however, a re-examination in the light of the phase-locking capabilities of neuronal aggregates along the auditory hierarchy. Indeed, the upper limit of temporal precision in phase-locked firing reduces with each ascending step in the auditory pathway, so that the ability of neurons to follow fast modulations reduces upstream the auditory hierarchy (Batra et al. 1989; Langner 1992; Joris et al. 2004), and therefore the specific frequency of the eliciting stimulus used to obtain the FFR may play a critical role in engaging multiple sources and a specific configuration of subcortical and cortical generators. Hence, capitalizing on the frequency-specific phase-locking capabilities along the auditory hierarchy, it has been observed that the relative contribution of subcortical and cortical sources to the scalp-recorded FFR varies systematically with stimulus frequency. In fact, the cortical contributions to the scalp-recorded FFR observed were restricted to the lowest

(fundamental) frequencies of the speech spectrum (100 Hz), and recent evidence demonstrated that this cortical contribution to the FFR disappears at frequencies higher than 150 Hz (Bidelman 2018). These findings challenge the assumption of the FFR as a correlate of subcortical sound encoding and support an emerging viewpoint in the literature that the FFR represents an integrated response of the entire auditory system (Kraus and White-Schwoch 2015; Kraus and Slater 2016), with its specific neural origins depending on the frequency of the eliciting sounds.

Developmental Issues: The FFR from Birth to Adulthood

The refinement and modulation of the encoding and representation of complex sounds in the cortico-subcortical auditory system, as reflected by the FFR, remain active and undergo stages of progression along the human life-span. The first FFR recording in human neonates was carried out by Gardi and colleagues in 1979 using low-frequency tone bursts (Gardi et al. 1979b), but it was not until three decades later when the neonates' adultlike capabilities to phase-lock to the incoming stimulus fundamental frequency were fully characterized (Jeng et al. 2010; Ribas-Prats et al. 2019). FFRs recorded in neonates have a similar response morphology to those from adults, in both the phase-locking to the periodicity of the stimulus waveform and its latency, thus confirming that the integrity of the subcortical auditory pathway can be assessed using FFRs from the first day of life at the maternity hospital room.

To understand the encoding and processing of complex sounds in infants, it is important to consider first the development of the auditory pathway during the gestational age. The inner ear and the cochlea become fully mature and functional by 5 months of gestation, which makes the fetus sensory and neurally capable to receive acoustic inputs from both its mother's body and from the external world. However, the only acoustic vibrations that reach the fetus are through the mother's womb, which filters out the input of higher frequencies and allows only the transmission of low-frequency sounds to the fetus. This influence of prenatal

listening experience on the neural development of auditory subcortical structures has been supported by studies showing that the FFR amplitude to the fundamental frequency of the eliciting stimuli was clearly observed in neonates (Ribas-Prats et al. 2019) and did not increase significantly in older infants (Anderson et al. 2015). On the other hand, the amplitudes of the FFR to higher frequencies (corresponding to the first formant and higher harmonics) are significantly smaller than the ones of the fundamental frequency (Ribas-Prats et al. 2019) and increase significantly with increasing age (Anderson et al. 2015). The mandatory delay of exposure to high frequencies until birth and the continued myelination of neural structures at the subcortical level during the first year of life may explain the different sensitivity to the input frequency content during the first years of life.

The encoding of spectral and temporal speech components becomes adultlike by the age of 6 months or around, period at which, according to electrophysiological and behavioral studies, the preference for the native language becomes evident. The auditory system suffers rapid maturational changes during the first months of age, followed by an overshoot during childhood (5–11 year old), and remained stable throughout adulthood until aging-related modulations come into effect (Skoe et al. 2015a).

Contrasting with the abundance of literature describing cortical responses in infants, very few studies have focused on the sound processing at subcortical stages of the auditory pathway in neonates. One remarkable attempt to characterize subcortical auditory processing of complex sounds during the first 3 months of age was by Jeng et al. (2016), who conducted a longitudinal study in which the FFR was recorded in a group of infants in two periods of time: during their first days of life (1–3 days after birth) and at the age of 3 months (Jeng et al. 2016). Although only 13 of the initial group of 44 were recorded at 3 months, the results suggested an improvement in pitch processing with increasing age. These findings are in line with a preliminary work by the same group in which the FFR was collected in one of their participants at 1, 3, 5, 7, and 10 months of age (Jeng et al. 2010). However, further

longitudinal follow-up studies are necessary to fully characterize the developmental stages the FFR may follow.

Effects of Experience-Dependent Plasticity on the FFR

As mentioned above, the FFR has gained recent interest in cognitive auditory neuroscience, as it allows investigation of the biological mechanisms and environmental conditions that modulate the encoding of complex sounds in the auditory hierarchy in service of human communication.

One of the most remarkable features of the FFR is its sensitivity to context-dependent contingencies and to real-time statistical properties of the stimulus. A number of studies have demonstrated that the FFR is able to capture the rapid statistical features of the incoming stimulation, disclosing the encoding of auditory regularities along the auditory hierarchy. In particular, it has been shown that the second harmonic of the FFR is enhanced for both local and global repetitions of a five-tone melody, thus indicating encoding of both global and local statistical regularities within the ongoing stimulation, and that regularity encoding mechanisms might be involved when an auditory object must be separated from background noise (Skoe and Kraus 2010b). In a similar vein, the use of an oddball stimulus sequence with consonant-vowel stimuli revealed that the FFR is not only enhanced for local regularities but also attenuated on its second harmonic in response to a deviant event (e.g., one with low local probability; Slabu et al. 2012). These findings were replicated and extended by subsequent studies, thus supporting the role of the entire auditory hierarchy in extracting statistical information from the acoustic background and demonstrating that context-dependent contingencies and learning-dependent plasticity interact in subcortical stages of the auditory hierarchy (Skoe et al. 2014). In a related account, it was further shown that not only stimulus predictability but also temporal predictability of the incoming stimulation enhances regularity encoding of the acoustic environment, thus indicating that context-dependent contingencies of the ongoing auditory input modulate the encoding of stimulus statistics

in the ascending auditory pathway (Gorina-Careta et al. 2016).

The neural sensitivity to stimulus statistics generalizes to more ecological conditions, in which sound patterns were embedded within a single uninterrupted sequence, as was demonstrated in a number of studies in which a series of musical notes were presented in random or patterned sequences. In the patterned sequences, the occurrence of a tone predicted with high accuracy the following one. By using this design, attenuated responses were obtained for the patterned condition compared to the random one, and the more enhanced were the subcortical responses to the patterned condition to the random one, the greater was the individual capability to learn the sequence (Skoe et al. 2013). This sensitivity to stimulus statistics is biased by prior experience and the expectations arising from this experience (Skoe et al. 2015b). Interestingly, the sensitivity to the contingencies of the incoming stimulation is not exclusive of adults but is already seen in children with good reading skills (Chandrasekaran et al. 2009). These results indicate that the whole auditory hierarchy is sensitive to the ongoing stimulus context and that prior experience modulates the responses to the incoming sounds.

Evidence for experience-dependent plasticity has also been provided by the results of short-term training studies, in which FFRs were recorded before and after a period of training (for a review, see Carcagno and Plack 2017). For example, as mentioned above, context-dependent contingencies interact with the effects of short-term training on the accuracy of the encoding of the fundamental frequency (F0) of sounds (Skoe et al. 2014), and, as a result of short-term F0 discrimination training, it has also been observed an improvement of the bilingual robustness of the subcortical temporal encoding (Carcagno and Plack 2011). FFR plasticity has also been investigated after the training on the identification of lexical tones (Song et al. 2008; Chandrasekaran et al. 2012) as well as using general speech-in-noise training protocols (Song et al. 2012). By using this latter one, it has been shown that the subcortical encoding of temporal information

is improved after training. The finding that subcortical auditory processing is not static but can be manipulated by training led to the hypothesis that sensory deficits caused by degraded sound processing could be improved by training. Indeed, it was shown that auditory training can alter the preconscious neural encoding of complex sounds by improving the neural synchrony in the auditory brainstem in children with learning disabilities (Russo et al. 2005).

Furthermore, the FFR is not only modulated by short-term auditory training but also by different auditory experiences, such as musical training or language exposure. The first study on the influence of musical training on the FFR was conducted by Musacchia and colleagues (Musacchia et al. 2007), where they demonstrated that musicians have earlier and larger FFRs than nonmusicians to both speech and musical stimuli presented in auditory and audiovisual conditions. Their work was extended by the observation that musicianship enhances the FFR tracking of pitch contours (Wong et al. 2007) and that this experience-dependent plasticity is shaped along the dimensions that are the most behaviorally salient for the listener (Bidelman et al. 2011). Musicians also have a more robust subcortical representation of acoustic stimuli in the presence of noise (Parbery-Clark et al. 2009) and enhanced encoding of speech syllables presented in a predictable condition relative to a variable condition than nonmusicians (Parbery-Clark et al. 2011), thus leading to the hypothesis that subcortical regularity encoding is shaped by musical training and may contribute to the musicians enhanced speech-in-noise perception. Interestingly, the neural changes produced by musical training during childhood are retained in adulthood, as the magnitude of the FFR correlates with how recently the training ceased (Skoe and Kraus 2012).

Language experience is another factor that strongly influences the encoding of speech sounds along the auditory pathway. Bilingual experience enhances the neural responses to the fundamental frequency of sounds (Krizman et al. 2015; Skoe et al. 2017) as well as the subcortical representation of pitch-relevant information (Krizman et al.

2012) and neural consistency, which correlates with both a better attentional control and language proficiency (Krizman et al. 2014). In addition, long-term experience with a tone language (such as Mandarin) sharpens the tuning characteristics of neurons along the pitch axis with enhanced sensitivity to linguistically relevant, rapidly changing sections of pitch contours (Krishnan et al. 2008). In summary, neural encoding of sounds in the subcortical auditory pathway, as revealed by means of the FFR, is shaped by long-term experience with language or music, thus supporting that early sensory processing can undergo experience-dependent plasticity (Fig. 2).

FFR in Challenging Conditions

Human auditory function in challenging conditions can be understood from different perspectives. First, the challenge can be imposed by external situations in which the acoustic signal is degraded by concurrent competing sound streams (i.e., listening in noise) or by room acoustics introducing echoes and reverberation, which necessarily hamper the intelligibility of speech signals. A serious challenge in listening, of an internal nature, is also imposed by hearing loss and even normal aging. A further challenge to central auditory processing is conveyed by clinical conditions, mostly neurodevelopmental, that have been shown to affect auditory, speech, and language perception. In all these domains, the FFR has played a significant role in characterizing the effects of the challenges in the neural encoding of complex, typically speech sounds and its consequences in listening, linguistic, and even cognitive competence.

Both noise- and reverberation-related changes in the FFR are shown in both the time and frequency domains. In particular, noise masks the spectral details of speech, reducing the contrast between the salient frequency features of the sound and the baseline noise (Russo et al. 2004; Li and Jeng 2011). In contrast, reverberation causes a smearing of the spectrotemporal details of the acoustic signal, thus producing a temporal overlap of time-frequency information which results in a systematic degradation in neural periodicity as it degrades the normal phase-locking ability of the FFR (Bidelman and Krishnan 2010). Interestingly,

Auditory Frequency-Following Responses, Fig. 2 Modulation of the FFR by auditory experience and context-dependent contingencies. The FFR to different acoustic stimuli is sensitive and can be modulated by a range of different auditory experiences, such as language exposure and musical training. In particular, this influence is so strong that it can be appreciated in the temporal representation of the FFR when comparing groups with different levels of exposure, for example, to two (bilinguals) instead to only one (monolinguals) language (a), or in participants with musical experience as compared to nonmusicians (b). The FFR is also highly sensitive to context-dependent contingencies (c) and to real-time statistical properties of the stimulus (d). In some cases, as the ones illustrated here, differences in the FFRs are not evident in the time domain but can be appreciated in the

spectral decomposition of the neural signal. The bottom left panel (c) depicts the spectral representation of the FFRs elicited to the same stimulus having three different contextual roles as a function of its probability of occurrence (i.e., as a low-probable [Deviant], red; high-probable [Standard], blue; control, black). Differences became clearly (and statistically) visible in the amplitude of the second harmonic. The bottom right panel (d) shows a similar approach to illustrate the effects of short-term statistics (stimulus repetition) on the FFR (first presentation in red; tone repetition in black). Differences between tone statistics (e.g., repetition) are clearly observed in the second harmonic. Figures adapted and reproduced with permission from (a) Krizman et al. (2012), (b) Skoe and Chandrasekaran (2014), (c) Slabu et al. (2012), and (d) Skoe and Kraus (2010b).

the two types of acoustic interference do not result in uniform impairment in the speech signal. Indeed, pitch (measured in the encoding of the fundamental frequency) and timbre (assessed by the spectral energy in higher harmonics and spectral envelope) are differentially affected and hence encoded in the FFRs. Little degradation in the FFR fundamental frequency is observed neither with noise nor reverberation, whereas higher harmonics degrade quickly with acoustic interference.

The encoding of speech sounds along the auditory hierarchy with acoustic interference is not stable across the life-span. Rather it naturally declines with age and is impaired in certain auditory disorders. The evoked responses for the three fundamental acoustic features intrinsic to speech sounds are shown to be inefficiently encoded, reduced, or delayed in different ways for distinct clinical populations compared to typically developing controls, but, overall, they all

lead to a weakness in the neural processes that are important for the appropriate auditory processing of the auditory signal. In particular, reduced representation of the fundamental frequency and the harmonics or delayed onset of the FFRs have been observed for children with learning problems (Cunningham et al. 2001) and/or with language deficits and reading disorders such as dyslexia (Banai et al. 2005, 2009; Banai and Ahissar 2006; Chandrasekaran et al. 2009; Anderson et al. 2010; Hornickel et al. 2012; Hornickel and Kraus 2013). Additionally, neural synchrony (timing) and phase-locking (frequency encoding) are also decreased in children with autistic spectrum disorders (Russo et al. 2008, 2009).

Conclusions

In this entry we have attempted to characterize the frequency-following response (FFR) as an auditory evoked potential which is called to play a relevant role in modern auditory cognitive neuroscience. By virtue of its “neurophonic” nature, its ability to reproduce the eliciting sound when played through a speaker, the FFR faithfully reveals how the fine-grained spectrotemporal features of complex auditory stimuli are analyzed and represented along the entire auditory system. Furthermore, by its multi-dimensional sensitivity to the individual’s experience with acoustic surroundings along the life-span, including long-term exposure to language, music, and noise but also short-term, dynamic processing of auditory streams, the FFR has demonstrated the profound plasticity of the auditory system in the service of auditory perception, the use of language, and communication. By characterizing the complex generating pattern of anatomical structures contributing to the FFR, from the cochlear nucleus to the inferior colliculus, the medial geniculate body of the thalamus, and the auditory cortex, studies with the FFR have revealed the auditory system to be the core of a neural network that interacts with the motor and reward systems to guide and refine our life in sound (Kraus and White-Schwoch

2015). Also, the FFR may have a major translational role in audiologic, neurodevelopmental, and educational domains. In the first place, the FFR recorded at a preschool age has been shown to predict performance across multiple domains of emergent literacy as measured 1 year later (White-Schwoch et al. 2015). Second, given these predictive capabilities of the FFR, one is tempted to speculate that a simple FFR recording at birth (Ribas-Prats et al. 2019) may give a snapshot into the speech-learning abilities on the neonate. Such a test could be routinely applied at the maternity unit, together with the universal newborn hearing screening, right after birth and could lead to early preventive intervention in babies at risk of speech acquisition or developmental delays (Kraus and White-Schwoch 2016). Finally, the FFR may provide a complementary tool in the practice of audiology to objectivize auditory perceptual deficits in patients with complaints about hearing loss in the presence of a normal audiogram and negative testing.

Definition

Auditory memory is the storage of information about sounds, including both acoustic features (sensory memory) and categorical information about sound categories and multi-sound structure.

Detailed Description

Auditory memory plays a critical role in various aspects of human activities, such as music, verbal learning, and communication. For example, when a person says, “I said ‘rice,’ not ‘lice,’” the listener must keep the word “rice” in auditory memory to compare it with the word “lice” afterward.

It is widely accepted that auditory memory can be partitioned into three components (Cowan 1984; Crowder 1976; Massaro 1975; Neisser 1967), which Massaro terms preperceptual auditory storage (known also as echoic memory), synthesized auditory memory, and generated abstract memory. Figure 1 illustrates these components and their relationships.

Preperceptual Auditory Storage

Preperceptual auditory storage retains the uncategorized representations of auditory inputs

Auditory Memory, Fig. 1 Three phases of auditory memory according to Massaro (1975)

that have not yet been fully processed (Massaro 1975) and is also referred to as short auditory storage (Cowan 1984). It is the auditory counterpart of what is thought of as iconic memory in the visual domain. Preperceptual auditory storage is the first step in auditory processing and starts right after an auditory stimulus enters perception. The duration of preperceptual auditory storage is very short. Most researchers agree that it lasts less than 300 ms. One compelling source of evidence for the duration of preperceptual auditory storage comes from the finding that when a sound is very short (e.g., less than 100 ms), it is still perceived as lasting for about a quarter of a second, which is considered to be the duration of preperceptual auditory storage (for a review see Cowan 1984).

Synthesized Auditory Memory

The auditory features stored in preperceptual auditory storage can be further analyzed to form integrated representations of sound. These integrated representations are considered to be stored in synthesized auditory memory (Massaro 1975). The term “synthesized” refers to the process in which auditory features such as pitch, loudness, and aspects of timbre are analyzed and combined into integrated auditory representations. The duration of the synthesized auditory memory appears to vary from less than 1 s up to 30 s, depending on how it is measured, but it is most often found to be several seconds (Cowan 1984).

The distinction between preperceptual auditory storage and synthesized auditory memory is supported by several lines of research, including backward masking, dichotic listening, and the suffix effect (Cowan 1984). One of the most convincing sources of evidence comes from a backward masking study by Kallman and Massaro (1979). Backward masking refers to the phenomenon that when two sounds are presented sequentially with a very short interval between them, the processing of the first sound (target) sustains interference from the second one (mask). Kallman and Massaro (1979) used two types of sound sequence: (1) standard tone, target tone, and mask (referred to as mask third or “M3”) and (2) standard tone, mask, and target tone (referred

to as mask second or “M2”). The participants needed to judge whether the target tone had a higher or lower frequency than the standard tone. In each type of sequence, the interval between the mask and its preceding tone (stimulus onset asynchrony or SOA) was varied, and the mask was either similar to the preceding tone or quite different from it (it was then a white noise). A prediction can be made on the basis of two forms of memory, preperceptual auditory storage and synthesized auditory memory. These two forms can be separately interfered with. In both types of trials, the comparison between the target and standard tones should be impaired by target-mask similarity at a very short SOA because at short SOAs, the similar mask interferes with preperceptual auditory storage of the preceding target tone. Additionally, in the M2 trials only, it is expected that the comparison is always impaired by a similar mask, regardless of the SOA. The reason is that the mask in this procedure comes between the standard and target tones and therefore can interfere with synthesized auditory memory of the standard tone. These expectations exactly match what was found; the target-mask similarity mattered only at short SOAs in the M3 condition, but it mattered at all SOAs in the M2 condition. This finding supports the distinction between preperceptual auditory storage and synthesized auditory memory.

Generated Abstract Memory

The integrated representations in synthesized auditory memory can be further processed to form abstract representations in generated abstract memory (Massaro 1975). The abstract representations are considered to be domain general, meaning that they do not carry information about specific sensory details. Thus, abstract representations generated from each sensory domain (hearing, vision, touch, and so on) are all stored together in the generated abstract memory.

In more recent literature, generated abstract memory is often referred to as “the focus of attention” and is reported to have a core capacity of three to five items when various memory strategies are controlled (Cowan 2001). It is thought that information must be saved in generated

abstract memory before high-level thinking about it can occur.

How Auditory Memory Is Used

Although auditory memory is usually partitioned into three phases, all three phases can be used in parallel to process auditory information. Suppose that you are sitting in a noisy airport reading and a stranger asks you what time it is. Even though you did not catch the words immediately, you can still extract the raw auditory information from the preperceptual auditory storage, except for the very last sounds that were masked by someone else nearby talking immediately afterward. The extracted information is then integrated into synthesized auditory memory, which can save the auditory information long enough for you to turn your attention away from the reading and toward the sounds. When your attention is focused on the sounds, you can analyze the sounds based on their memory, using your existing language knowledge. You form a generated abstract memory of what the stranger meant, and you can then respond with the correct time if you have it. This is a typical scenario in which all three phases of auditory memory work together to serve the auditory processing involved in social interactions.

Definition

The process of extracting acoustic features from sound waves and partitioning them into meaningful groups.

Detailed Description

Introduction

Traveling pressure waves (i.e., sounds) are produced by the movements or actions of objects. So sounds primarily convey information about *what is happening* in the environment. In addition, some information about the structure of the environment and the surface features of objects can be extracted by determining how the original (self-generated or exogenous) sounds are filtered or distorted by the environment (e.g., the notion of “acoustic daylight,” Fay 2009). In this entry we consider how the auditory systems process sound signals to extract information about the environment and the objects within it.

The auditory system faces a number of specific challenges which need to be considered in any account of perceptual organization: (1) sounds unfold in time; we can’t (normally) go back to reexamine them. Therefore, information must be extracted and perceptual decisions made in a timely manner. (2) The information contained within sounds generally requires processing over many timescales in order to extract their meaning (Nelken 2008). For example, a brief impulsive sound may tell the listener that two objects have been in collision, but a series of such sounds is needed in order for the listener to know that someone is clapping rather than walking. (3) Many objects of interest generate sounds intermittently. Therefore, some means for associating temporally discontinuous events are required. (4) Sound pressure waves are additive; what the ear receives is a combination of all concurrently active sound sources and their reflections off any hard surfaces. Many animals and birds communicate acoustically in large social groups, making the problem of source separation particularly tricky (Bee 2012). Despite these challenges, if the auditory system is to provide meaningful information about individual objects in the environment (e.g., potential mates or aggressors), it needs to partition the acoustic features into meaningful groups, a process known as *auditory perceptual organization* or *auditory scene analysis* (Bregman 1990).

Grouping Principles

Auditory Events

Natural environments typically contain many concurrent sound sources, and even isolated sounds can be rather complex, e.g., animal vocalizations contain many different frequency components, and both the frequencies of the components and their amplitudes can vary within a single sound. The problem for the auditory system is to find some way of correctly associating the features which originate from the same sound source. The classical view of this process is that the cochlea decomposes the incoming composite sound waveform into its spectral components, generating a topographically organized array of

signals which sets up the *cochleotopic* (or *tonotopic*) organization found throughout most of the auditory system, up to and including the primary auditory cortex (Zwicker and Fastl 1999). Other low-level features such as onsets, amplitude and frequency modulations, and binaural differences are extracted subcortically and largely independently within each frequency channel (Oertel et al. 2002). These acoustic features are bound together to form auditory *events* (Bertrand and Tallon-Baudry 2000; Zhuo and Yu 2011) or *tokens* (Shamma et al. 2011), i.e., discrete sounds that are localized in time and perceived as originating from a single sound source (Ciocca 2008). Events are subsequently grouped sequentially into patterns, streams, or perceptual objects.

Gestalt Grouping Principles

Perceptual decisions regarding the *causes* of the signals received by the sensors must in general be made with incomplete information (Brunswick 1955). Therefore, potential solutions need to be constrained in some way, e.g., by knowledge about likely sound sources (Bar 2007) or by expectations arising from the recent context (Winkler et al. 2012). In his seminal book, Bregman (1990) pointed out that many such constraints had already been identified by the Gestalt school of psychology (Köhler 1947) early in the twentieth century. The core observation of Gestalt psychology was that individual features form larger perceptual units, which have properties not present in the separate components (von Ehrenfels 1890), and, conversely, that the perception of the components is influenced by the overall perceptual structure (Wertheimer 1912). Focusing primarily on visual stimuli, the Gestalt psychologists described the following grouping principles (laws of perception), here discussed in terms of auditory grouping.

(a) **Good continuation:** Smooth continuous changes in perceptual attributes favor grouping, while abrupt discontinuities are perceived as the start of something new. This principle can operate both within and between individual events.

- (b) **Similarity:** Similarity between the perceptual attributes of successive events (e.g., pitch, timbre, location) promotes grouping (Bregman 1990; Moore and Gockel 2002, 2012). Similar to the perception of visual motion (Weiss et al. 2002), it appears that it is not so much the raw difference that is important, but rather the *rate of change*; the slower the rate of change between successive sounds, the more similar they are judged (Winkler et al. 2012). In other words, in the auditory modality, *similarity* and *good continuation* may be equivalent.
- (c) **Common fate:** Correlated changes in features promote grouping, recently formalized as *temporal coherence*, i.e., feature correlations within time windows that span periods longer than individual events (Elhilali et al. 2009; Shamma et al. 2011).
- (d) **Disjoint allocation (or belongingness):** Refers to the principle that each element of the sensory input is only assigned to one perceptual object, e.g., exclusive border assignment in Rubin's face-vase illusion. However, although generally true, this principle is sometimes violated in auditory perception, e.g., in *duplex perception*, the same sound component can contribute to the perception of a complex sound as well as being heard separately (Rand 1974; Fowler and Rosenblum 1990).
- (e) **Closure:** Objects tend to be perceived as whole even if they are not complete, e.g., a glide continuing through a masking noise if the glide offset is masked (Miller and Licklider 1950; Riecke et al. 2008). This applies more generally to the perception of global patterns (or "Gestalts"), e.g., individual notes are subsumed into a melodic pattern (McDermott and Oxenham 2008) and predictable individual speech sounds are perceived as present even if they are masked or missing (Warren et al. 1988). The auditory system is extraordinarily sensitive to repeating patterns and appears to readily use this cue to parse complex scenes (Winkler 2007; McDermott et al. 2011).

An important concept that emerges from the idea of a “Gestalt” as a pattern is that of predictability. In the case of auditory perception, this refers to expectancies about sound events that have not yet occurred. By detecting patterns (or feature regularities) in the acoustic input, the brain can construct representations that allow it to anticipate or “explain away” (Pearl 1988) future events. In this way Gestalt theory connects to the ideas of unconscious inference (Helmholtz 1885) and perception as hypothesis formation (Gregory 1980).

Auditory Objects

While visual objects are widely accepted as fundamental representational units, the notion of an auditory object is less well established, and there is as yet no universal agreement on how they should be defined, e.g., see Kubovy and Van Valkenburg (2001), Griffiths and Warren (2004), Winkler et al. (2006), Shinn-Cunningham (2008). Based on the Gestalt principles and ideas of perceptual inference, outlined above, Winkler et al. (2009) proposed a definition of an auditory perceptual object as a predictive representation, constructed from feature regularities extracted from the incoming sounds. These object representations are temporally persistent and encode distributions over featural and temporal patterns, determined by the current context. The consolidated object representation therefore refers to *patterns of sound events*; individual sound events are processed within the context of the whole to which they belong. This definition of an auditory perceptual object is compatible with the definition of an auditory stream, as a coherent sequence of sounds separable from other concurrent or intermittent sounds (Bregman 1990). However, whereas the term “auditory stream” refers to a phenomenological unit of sound organization, with separability as its primary property, the definition proposed by Winkler et al. (2009) emphasizes the extraction and representation of the unit as a pattern with predictable components (Winkler et al. 2012). While the usage of the term object is not universally accepted within the auditory domain, we will use it in this entry as defined by Winkler et al. (2009).

Auditory Scene Analysis

In order to determine the perceptual qualities of individual sound events, the brain must first bind their component features even though the number of concurrent auditory objects and which features belong to each is unknown a priori; this must be inferred incrementally from the ongoing sensory input. Therefore, it is clear that the auditory system needs to use (top-down) contextual information to guide its grouping decisions and some means for evaluating these decisions and revising them in the event that they prove to be incorrect. In the currently most widely accepted framework describing perceptual sound organization, auditory scene analysis, Bregman (1990) proposes two separable processing stages. The first stage is suggested to be concerned with partitioning sound events into potential groups based primarily on featural similarities and differences. The second stage, within which prior knowledge and task demands exert their influence, is a competitive process between candidate organizations that determines which one is perceived. Within this framework there are two types of grouping: *simultaneous* grouping based on concurrent cues and *sequential* grouping based on contextual temporal cues. For the reasons outlined above, these two are not really distinct (simultaneous cues are influenced by prior sequential grouping, e.g., Darwin et al. (1995) and Bendixen et al. (2010b), just as sequential grouping is influenced by the perceptual qualities of individual events (simultaneous grouping) (Bregman 1990); nevertheless, they provide a useful starting point for models of auditory scene analysis.

Simultaneous Grouping

In the absence of sequential grouping cues, there are some features which automatically trigger the formation of individual sound events; for reviews see Darwin and Carlyon (1995) and Ciocca (2008). Common onsets and offsets form clear temporal boundaries, and the strategy adopted by the auditory system is to match onsets to offsets (including similarities between features and temporal proximity) in order to segregate perceptual events (Nakajima et al. 2000). Harmonicity

(i.e., the presence of frequency components which are integer multiples of a common fundamental frequency) is another important grouping cue (Darwin and Carlyon 1995). For example, when one component of a complex harmonic tone is mistuned, listeners perceive two concurrent sounds, a complex tone consisting of the harmonically related components and a pure tone, corresponding to the mistuned component (Moore et al. 1986). However, not all acoustic features trigger concurrent grouping, e.g., a location cue (common interaural time differences) between a subset of frequency components within a single sound event does not generate a similar segregation of component subsets within individual sound events (Culling and Summerfield 1995).

Another important strategy for segregating sound events is template matching. If people have prior knowledge of events, then it is possible to hear them out. This effect was exploited in the many double-vowel experiments used to test the influence of different acoustic features, e.g., Assmann and Summerfield (1990) and Summerfield and Assmann (1991), and even in the absence of featural differences, it was shown that known vowel sounds can be identified well above chance (Assmann and Summerfield 1989). This template-matching phenomenon appears to be rather general and applies to any sound that is repeated. The auditory system is very sensitive to repetition (Teki et al. 2011). If a previously unheard sound is repeated against a different background, then it can be segregated and identified significantly above chance, even with only a single repetition, and even if many of usual grouping cues are absent (McDermott et al. 2011). Similarly, arbitrary repeated noise segments can be rapidly learnt within a few trials (Agus et al. 2010).

Models of Event Formation

Many models have been developed to investigate simultaneous grouping and the segregation of perceptual events, e.g., see models described in Wang and Brown (2006). A model of auditory saliency which used low-level cues of spectral and temporal contrast to highlight salient events

in continuous noisy soundscapes predicted human event detection very well (Kayser et al. 2005). Temporal contrasts effectively highlight onsets and offsets, while spectral peaks carry information about the resonances of sound sources and to some extent their identity (von Kriegstein et al. 2007). The segregation of overlapping events using pitch cues has been widely explored (c.f. Pitch Perception, Models), e.g., for explaining enhanced double-vowel segregation (de Cheveigne et al. 1995). The segregation of events using repetition was shown to be possible in principle by using a combination of cross-correlation and averaging to incrementally build a representation of the repeated target (McDermott et al. 2011). Because of the importance of longer-term context on grouping, none of these models provide general solutions to the problem of auditory scene analysis; nevertheless, they provide important building blocks in this process.

Sequential Grouping

Sequential grouping generally conforms to the Gestalt principles of *similarity/good continuation* and *common fate*. In contrast to concurrent grouping, sequential grouping is necessarily based on some representation of the preceding sounds; for reviews, see (Moore and Gockel 2002; Carlyon 2004; Haykin and Chen 2005; Snyder and Alain 2007; Ciocca 2008; Shamma and Micheyl 2010; Shamma et al. 2011; Moore and Gockel 2012). Most studies of this class of grouping have used sequences of discrete sound events to investigate the influences of acoustic features and temporal structure. In the most widely used experimental approach (termed the auditory streaming paradigm), sequences of alternating sound events differing in some feature(s) are presented to listeners (van Noorden 1975). When the feature separation is small and/or they are delivered at a slow pace, listeners predominantly hear a single *integrated* stream containing all the sounds. With large feature separation and/or fast presentation rates, listeners report hearing the sequence separate out into two *segregated* streams. In this there is a cue trade-off: smaller feature differences can be compensated with higher presentation rates and

vice versa (van Noorden 1975). Differences in various auditory features, including frequency, pitch, loudness, location, timbre, and amplitude modulation, have been shown to support auditory stream segregation (Vliegen and Oxenham 1999; Grimault et al. 2002; Roberts et al. 2002). Thus it appears that sequential grouping is based on perceptual similarity, rather than on specific low-level auditory features (Moore and Gockel 2002, 2012). Temporal structure has also been suggested as a key factor in segregating streams either by guiding attentive grouping processes (Jones 1976; Jones et al. 1981; Large and Jones 1999) or through temporal coherence that binds correlated component features in the auditory input (Elhilali et al. 2009; Shamma and Micheyl 2010; Shamma et al. 2011, 2013).

Models of Auditory Streaming

Early models of auditory streaming, e.g., Beauvois and Meddis (1991), focused on the relationship between frequency differences and event rate and the proposal that streaming could be explained almost exclusively by peripheral channeling mechanisms (Hartmann and Johnson 1991) or the degree of overlap between neural responses to each of the alternating tones, e.g., McCabe and Denham (1997). In these models the perceptual decision was represented by levels of activation across a spatial array of neurons; see also Micheyl et al. (2005) for a similar interpretation of neural activity in primary auditory cortex. A different approach in which grouping is signaled by temporal correlations within network responses was proposed by Wang, Brown, and colleagues (Brown and Wang 2006; Wang and Chang 2008). For example, the model proposed by Wang and Chang (2008) consists of a 2-dimensional array of oscillators with one dimension representing frequency and the other external time. Units are connected by local excitatory connections and by global inhibition. Characteristic results of classical auditory streaming experiments (van Noorden 1975) are simulated by including strong local excitatory connections (encouraging synchronization) and weaker long-range connections (which are easily overcome by inhibition and therefore encourage

desynchronization). Sensitivity to event rate is modeled by dynamic weight adjustments. However, while the representation of grouping is different from the models previously outlined, this model also depends on peripheral channeling and the degree of overlap in the incoming activity patterns to determine its grouping decision.

A similar focus on temporal coherence (in this case the average correlation within a sliding window 50–500 ms in duration) is seen in the model of streaming proposed by Elhilali and colleagues, e.g., Elhilali and Shamma (2008) and Shamma et al. (2011) (Note, Figs. 6 and 9 in this entry have incorrect colour scale labels (0% and 100%, interchanged; Shamma and Elhilali (2013)). The computational model developed by Elhilali and Shamma (2008) extracts multiple features from the incoming acoustic input including frequency, pitch, direction, and spectral shape and assigns the resulting activity patterns to one of two clusters which come to represent the properties of the events in each stream. The temporal coherence measure is used to determine which components should be grouped. The clusters compete to incorporate each event, and the winning cluster uses the event features (as determined by the grouping process) to refine its representation. These correlation-based models overcome a problem faced by the population separation account of streaming (Micheyl et al. 2005) that predicted widely separated components would be segregated even if they overlapped in time, which is not the case (Elhilali et al. 2009). They also provide a means for binding the component features of an event, not considered in the earlier models. Later refinements to the temporal coherence account of streaming (Shamma et al. 2011, 2013), included the strong claims that (a) feature binding occurs only with attention, i.e., attention is responsible for grouping features that belong to the foreground object, c.f. (Treisman 1998), and (b) all other features remain ungrouped in an undifferentiated background. However, the proposed role of attention in feature binding has long been debated in the visual domain, e.g., Duncan and Humphreys (1989), and it is not consistent with the results of experiments testing feature binding in the absence of attention by

recording auditory event-related potentials (AERP) in response to rare feature combinations (Takegata et al. 2005; Winkler et al. 2005a).

Competition and Selection

The models described above all conform to the assumptions that in response to alternating two-tone sequences, (a) auditory perception always starts from the integrated organization and (b) that eventually a stable final perceptual decision is reached (Bregman 1990). However, it has been found, when listeners report their percepts continuously while listening to such sequences for long periods, that perception fluctuates between different perceptual organizations (Winkler et al. 2005b; Pressnitzer and Hupe 2006). Perceptual switching occurs in all listeners and for all combinations of stimulus parameters tested (Anstis and Saida 1985; Roberts et al. 2002; Denham and Winkler 2006; Pressnitzer and Hupe 2006; Schadwinkel and Gutschalk 2011; Denham et al. 2012), even combinations very far from the ambiguous region identified by van Noorden (1975). Furthermore, for stimuli with parameters that strongly promote segregation, participants often report hearing segregation first (Deike et al. 2012; Denham et al. 2012). It has also been found that perceptual organizations other than the classic integrated and segregated categories may be reported (Bendixen et al. 2010a, 2012; Böhm et al. 2012; Denham et al. 2012; Szalárdy et al. 2012), showing that auditory perceptual organization in response to alternating two-tone sequences is multistable (Schwartz et al. 2012).

The notion of perceptual multistability is challenged by everyday subjective experience of a world perceived as stable and continuous and by experimental results obtained by averaging over the reports of different listeners, which generally show that within the initial 5–15 s of two-tone sequence, the probability of reporting segregation monotonically increases (termed the buildup of auditory streaming) (but see Deike et al. (2012)). For these reasons it has been suggested that perceptual multistability observed in the auditory streaming paradigm may be simply a consequence of the artificial stimulation protocol used. However, there is a growing body of experimental data

supporting the existence of multistability and just as visual multistability has provided new insights into visual processing, e.g., Kovacs et al. (1996); it seems likely that understanding spontaneous changes in the perception of unchanging sound sequences will help throw new light on auditory perception.

Modeling Multistability in Auditory Streaming

Multistability of auditory perceptual organization cannot be explained by any of the theories or models outlined above, which all have essentially one fixed attractor. Models of visual multistability have a longer history, e.g., Laing and Chow (2002); Shpiro et al. (2009); van Ee (2009). These models typically contain three essential components (Leopold and Logothetis 1999): (a) mutual inhibition between competing stimuli to ensure *exclusivity* (i.e., perceptual awareness generally switches between the different alternatives rather than fusing them), (b) adaptation to ensure the observed *inevitability* of perceptual switching (the dominant percept cannot remain dominant forever), and (c) noise to account for the observed *stochasticity* of perceptual switching (successive phase durations are largely uncorrelated, and the distribution of phase durations resembles a gamma or log-normal distribution) (Levelt 1968). The questions for auditory multistability are what are the competing entities, and what form does this competition take in order to explain dynamic nature of perceptual awareness reported by listeners.

The computational model of auditory multistability proposed by Mill et al. (2013) is based on the idea that auditory perceptual organization rests on the discovery of recurring patterns embedded within the stimulus, constructed by forming associations (links) between incoming sound events and recognizing when a previously discovered sequence recurs and can thus be used to predict future events. These predictive representations, or *proto-objects* (Rensink 2000; Winkler et al. 2012), compete for dominance with any other proto-objects which predict the same event (a form of local competition) and are the candidate set of representations that have the potential to become the perceptual objects of

conscious awareness. This model accounts for the emergence of, and switching between, alternative organizations; the influence of stimulus parameters on perceptual dominance, switching rate, and perceptual phase durations; and the buildup of auditory streaming. In a new sound scene, the proto-object that is the easiest to discover determines the initial percept. Since the time needed for discovering a proto-object depends largely on the stimulus parameters (i.e., to what extent successive sound events satisfy/violate the *similarity/good continuation* principle), the first percept strongly depends on stimulus parameters. However, the duration of the first perceptual phase is independent of the percept (Hupe and Pressnitzer 2012), since it depends on how long it takes for *other* proto-objects to be discovered (Winkler et al. 2012). The model also accounts for the different influences of similarity and closure on perception; the rate of perceptual change (similarity/good continuation) determines how easy it is to form the links between the events that make up a proto-object, while predictability (closure) does not affect the discovery of proto-objects, but can increase the competitiveness (salience) of a proto-object once it has been discovered (Bendixen et al. 2010a).

Neural Correlates of Perceptual Organization

Neural responses to individual sounds are profoundly influenced by the context in which they appear (Bar-Yosef et al. 2002). The question is to what extent the contextual influences on neural responses reflect the current state of perceptual organization. This question has been addressed by a number of studies ranging in focus from the single neuron level (c.f. stimulus-specific adaptation) to large-scale brain responses (c.f. auditory evoked potentials), and the results provide important clues about the processing strategies adopted by the auditory system.

Studies investigating single neuron responses to alternating tone sequences, e.g., Fishman et al. (2004), Bee and Klump (2005), Micheyl et al. (2005), and Micheyl et al. (2007), have shown

an effect called *differential suppression*, i.e., at the start of the sequence, the neuron responds to both tones, but with time the response to one of the tones (typically corresponding to the best frequency of the cell) remains relatively strong, while the response to the other tone diminishes. Since neuronal sensitivity to frequency difference and presentation rate was found to be consistent with the classical van Noorden (1975) parameter space, it was claimed that differential suppression was a neural correlate of perceptual segregation (Fishman et al. 2004). This was supported by the finding that spike counts from neurons in primary auditory cortex predict an initial integration/segregation decision closely matching human perception (Micheyl et al. 2005; Bee et al. 2010). However, differential suppression does not account for perceptual multistability or for the perception of overlapping tone sequences (Elhilali et al. 2009); therefore, while differential suppression may be a necessary component of the auditory streaming process, it does not provide a complete explanation.

Auditory event-related brain potentials (AERPs) represent the synchronized activity of large neuronal populations, time locked to some auditory event. Because they can be recorded noninvasively from the human scalp, they have been widely used to study the brain responses accompanying auditory stream segregation; c.f. auditory event-related potentials, especially long-latency AERP responses. Three AERP components are of particular relevance in this regard: (a) the “object-related negativity” (ORN) which signals the automatic segregation of concurrent auditory objects (Alain et al. 2002), (b) the amplitude of the auditory P1 and N1 which varies depending on whether the same sounds are perceived as part of an integrated or segregated organization (Gutschalk et al. 2005; Szalárdy et al. 2013), and c) the mismatch negativity (MMN; Näätänen et al. 1978) which has been used as an indirect index of auditory stream segregation, e.g., Sussman et al. (1999); Nager et al. (2003); Winkler et al. (2003a); Gutschalk et al. (2005).

The detection and representation of regularities by the brain, as indexed by the MMN, provided the basis for the definition of an auditory object

proposed by Winkler et al. (2009). Using evidence from a series of MMN studies, they defined an auditory object as a perceptual representation of a possible sound source, derived from regularities in the sensory input (Winkler 2007, 2010) that has temporal persistence (Winkler and Cowan 2005) and can link events separated in time (Näätänen and Winkler 1999). This representation forms a separable unit (Winkler et al. 2006) that generalizes across natural variations in the sounds (Winkler et al. 2003b) and generates expectations of parts of the object not yet available (Bendixen et al. 2009).

It should be pointed out that while traditional psychological accounts of auditory perceptual organization implicitly or explicitly refer to representations of objects, there are models of auditory perception which are not concerned with positing a representation directly corresponding to auditory objects. The hierarchical predictive coding model of perception, e.g., Friston and Kiebel (2009), includes predictive memory representations, which are in many ways compatible with the notion of auditory object representations (Winkler and Czigler 2012), but no explicit connection with object representations is made. Shamma and colleagues' temporal coherence model of auditory stream segregation (Elhilali and Shamma 2008; Elhilali et al. 2009; Shamma et al. 2011, 2013) provides another way to avoid the assumption that object representations are necessary for determining sound organization; instead it is proposed that objects are essentially whatever occupies the perceptual foreground and exist only insofar as they *do* occupy the foreground. In summary, there is currently little consensus on the role of auditory object representations in perceptual organization, and the importance placed on object representations by the various models and theories differs markedly.

fMRI studies of auditory streaming have found neural correlates in a number of brain regions. In one of the earliest studies, Cusack (2005) failed to find differential activity in auditory cortex corresponding to perceptual organization into one or two streams, but he did find such activity in the intraparietal sulcus, an area associated with

cross-modal processing and object numerosity. Shortly afterwards Wilson et al. (2007) showed that auditory cortical activity increased with increasing frequency difference and that as the frequency difference increased, the cortical response changed from being rather phasic (i.e., far stronger at the onset of the sequence) towards a more sustained response throughout the stimulus sequence. Taking a closer look at the dynamics of cortical activity associated with perceptual switching, Kondo and Kashino (2009) showed that both auditory cortex and thalamus are involved, with an increase in thalamic activity preceding that in cortex associated with a switch from the nondominant to the dominant percept and, conversely, an increase in cortical activity preceding that in thalamus associated with a switch from the dominant to the nondominant percept. They also found differential activation in posterior insular cortex and in the cerebellum. Interestingly, activations in the cerebellum and thalamus are negatively correlated in auditory streaming, with the left cerebellar activation level increasing with the rate of perceptual switching and thalamus (medial geniculate) decreasing (Kashino and Kondo 2012). Consistent with these findings, Schadwinkel and Gutschalk (2011), using a different stimulus paradigm which allowed them to influence the timing of perceptual switching, found transient auditory cortical activation associated with perceptual switching and a further transient activation in inferior colliculus, although whether the inferior colliculus is responsible for triggering switching or simply reflects the transient switching activation in cortex is not clear. In summary, neural correlates of auditory streaming have been found in many areas within the auditory system and beyond, suggesting that creating and switching between alternative perceptual organizations involve a broadly distributed network within the brain.

Conclusions and Open Questions

The Gestalt principles and their application to auditory perception instantiated in Bregman's

(1990) two-stage auditory scene analysis framework provided the initial basis for understanding auditory perceptual organization, and recent proposals have extended this framework in interesting ways. Nevertheless, there remain many unanswered questions and there have been few, if any, attempts to build neuro-computational models capable of dealing with the complexity of real auditory scenes in which grouping and categorization cues are not immediately available; however, see (Yildiz and Kiebel 2011). Feedback connections are pervasive within the auditory system, including all stages of the subcortical system, yet to our knowledge no models include such connections. Although fMRI results are useful for identifying regional involvement, detailed understanding of the neural circuitry involved in auditory perceptual organization is sketchy, and the neural representations of auditory objects and perceptual organization are unknown. Even the role of primary auditory cortex remains something of a mystery, e.g., see Nelken et al. (2003) and Griffiths et al. (2004); perhaps studying the switching of perceptual awareness between different representations in awake behaving animals will help to elucidate the representations and processing strategies adopted by cortex.

Definition

The precedence effect is a well-studied phenomenon in spatial hearing that is related to how we localize sounds accurately in everyday settings. Specifically, when two sound sources reach a listener close together in time, listeners often hear a single “fused” image whose perceived direction is near the location of the first-arriving sound.

Detailed Description

The Effects of Room Acoustics on Auditory Spatial Cues

The signals reaching the listener’s ears directly from a sound source convey information about the source’s location (Blauert 1997; Schnupp et al. 2010). However, in ordinary

settings, soon after the direct sound reaches the listener, reflected sound arrives from random directions, coming off of walls, floors, and other reflective surfaces. This reflected sound energy adds acoustically to the direct sound before entering each ear, changing the total signal reaching the ear (e.g., see Allen and Berkley 1979). The content of this reflected sound energy depends on the geometry of the listening space, the positions of objects in the space, and the location and orientation of the listener. Moreover, the reflected sound energy differs at the left and right ears. As a result, this late-arriving sound distorts the spatial information conveyed by the direct sound, degrading the spatial cues in the total signal. As a result, the acoustic location information in the signals a listener hears in everyday settings is less reliable after an initial “clean glimpse” of the direct sound that happens at sound onset, before the reflected energy arrives.

The Precedence Effect

Perceptually, judgments of the direction of a sound source depend strongly on spatial information in the onset of sound and relatively weakly on spatial information in later-arriving portions of sound (e.g., see Brown and Stecker 2010). This phenomenon is known as the precedence effect (Wallach et al. 1949; Zurek 1987; Litovsky et al. 1999). Given that in ordinary listening spaces the onset of the sound has the most reliable information about source direction, the precedence effect is thought to be one of the reasons why listeners are relatively good at judging source location even when listening in rooms.

The precedence effect has been studied extensively with pairs of clicks (one leading and one lagging); for such brief stimuli, the precedence effect is strongest when the leading click precedes the lagging click by 1–5 ms and then rapidly becomes weaker (so that listeners start to hear the second click as a separate event and then begin to localize it with increasing accuracy; see Blauert 1997). For more “natural” sounds, like speech or music, the precedence effect persists for tens of ms. Many researchers argue that the precedence effect has a longer time course for ongoing signals because they can be thought of

as containing multiple “onsets” due to local energy fluctuations, each of which can add to the precedence effect (e.g., see Zurek 1980).

Mechanisms of the Precedence Effect

Although the precedence effect is often discussed as a single psychophysical phenomenon, many different mechanisms likely contribute to the dominance of early spatial information on later-arriving information. For instance, the most peripheral portion of the auditory system, the auditory nerve, responds more vigorously at the onset of a sound than to later-arriving portions of a sound. This peripheral adaptation helps explain why a lagging sound that arrives within a few milliseconds of a leading sound does not convey strong spatial cues (Hartung and Trahiotis 2001). However, there are numerous studies that show that the perceptual dominance of the leading sound extends beyond very brief lead-lag delays that can be fully explained by peripheral adaptation. It is likely that microcircuitry in the brainstem contributes to the precedence effect at longer lead-lag delays through some type of inhibition triggered by the leading sound (Xia and Shinn-Cunningham 2011).

Definition

Auditory processing in insects serves to extract relevant information from acoustic signals about identity and location of acoustic objects, usually in the context of mate attraction and predator avoidance. For this goal, insects process spectral information from the carrier frequency of a signal and obtain temporal information from the sound's amplitude modulation pattern (the envelope). Auditory processing in insects is constrained by size in several aspects: first, the signal often contains ultrasonic frequencies due to small sender size; second, for localization, insects have only poor directional cues because of the small distance between their ears; and third, due to their small brains, the auditory processing capacity is limited to a small number of neurons.

Detailed Description

Overview and Background

Large Diversity of Hearing Insects and their Ears

The sense of hearing has evolved in vertebrates and arthropods, and hearing organs are known from several orders of insects. Ears have evolved in rather different locations of their body, not only on the head but also on the thorax, abdomen, and even wings and legs (Fig. 1a, Fullard and Yack 1993). Consequently, numerous neuronal substrates for the processing of acoustic information are known that evolved from a mechanosensory modality employed in a different context (proprioception by chordotonal organs; Meier and Reichert 1990; van Staaden and Römer 1998). In insects, two types of ears are known that are sensitive to two different physical attributes of sound, that is, the movement of particles in an elastic medium: tympanal ears that are specialized to sense changes in sound pressure and antennae or filiform hairs that are sensitive to particle velocity (Fig. 1b–d, Michelsen 1979).

Goals of Hearing and Auditory Processing

The ability to hear sound and to extract relevant information from an acoustic signal has evolved in three functional contexts. Notably, the production of sound alone is not a sufficient indicator of hearing ability as many insects produce defensive sounds when threatened (e.g., Bura et al. 2011). Conversely, numerous insects can hear sound but are themselves mute (Riede 1987; Riede et al. 1990).

Acoustic Communication

In many species the perception of acoustic signals occurs in the context of acoustic communication for mate recognition and mate localization. The most prominent examples stem from grasshoppers, crickets, and bushcrickets (orthoptera), but cicadas and moths have also evolved elaborate acoustic signals. A major goal of intersexual acoustic communication is to discriminate conspecific from heterospecific signals which helps to avoid fitness losses (Fig. 2). Sexual selection by

female choice for song signals of particularly attractive mating partners is also well known (von Helversen and von Helversen 1994; Andersson and Simmons 2006). Insects employ very stereotyped signals for acoustic communication, the production and recognition of which has a strict innate basis (Bentley and Hoy 1972, von

Helversen and von Helversen 1975a, b, 1987). For this reason, the acoustic communication of grasshoppers, crickets, and bushcrickets has served as a model system to study the mechanisms of neuronal processing within the auditory pathway by carefully designed behavioral experiments and recordings of neuronal activity of

single cells (Schildberger and Elsner 1994; Huber et al. 1989; Gerhardt and Huber 2002).

Since the nervous system of insects is small, all computations must be performed by relatively few neurons. This likely imposes a strong pressure for an efficient and sparse representation of the external world. A big advantage of investigating nervous system processes via the study of communication signals is that an animal's "external world" can be reduced to a manageable set of relevant stimuli, the stimulus space. This rather small set of highly relevant stimuli allows one to characterize how the stimuli are represented

within the nervous system and how these representations are transformed at different stages of processing.

To allow for successful communication, signal properties must be matched to the sensory characteristics of receivers. A straightforward example is the frequency tuning of a cricket female's ears to the narrowband signals of the males (see Fig. 2g, h). However, since in many species the temporal pattern of communication signals conveys the species-specific information, sender and receiver should be matched not only for carrier frequency but also for temporal characteristics.

Auditory Processing in Insects, Fig. 2 Acoustic communication in grasshoppers and crickets. (a, f) A sender, the male, produces a specific sound signal that is transmitted and perceived by a receiver, the female. (a) In some grasshoppers, the female responds to the male with her own song (upper trace). Songs of males and females have different pulse shapes (lower traces). (b, c) The power spectra differ between males (b) and females (c) in relative content of low (L)- and high (H)- frequency components. (d, e) Females and males respond selectively to the relative content of low- and high-frequency components in a signal. (d) Females prefer the combination of low and high components as they occur in the male song (as in

b). (e) Males prefer signals with only low-frequency components as they are typical for a female song (as in c). (g) The spectral content of a song of a cricket as in (f) is narrowly tuned to a peak frequency (5.0 kHz). (h) Auditory tuning for the specific carrier frequency of a conspecific song for different species of crickets (frequency axis was normalized to the respective best frequency; P.p. *Paroecanthus podagrosus*, G.b. *Gryllus bimaculatus*, G.c. *G. campestris*). Note the differences in the sharpness of tuning ((a–e) From von Helversen and von Helversen 1997; (f) modified from Huber 1992; (g) modified from Montealegre-Z et al. 2011; and (h) from Schmidt et al. 2011, with permission)

Here, a new problem arises: temperature. Since the function of neurons and muscles is strongly temperature-dependent (Janssen 1992; Robertson and Money 2012) and in general insects' body temperatures vary directly with ambient temperature, a signal's temporal pattern will vary with ambient temperature. This creates a recognition problem for the receiver's auditory system, in particular, if sender and receiver differ in their body temperatures (von Helversen and von Helversen 1987; Gerhardt and Huber 2002; Ronacher et al. 2004).

Detection and Avoidance of Predators

Although hearing in insects evolved more than 200 million years ago (MYA), the appearance of bats about 60 MYA sparked an explosion of insect species with ears (Fig. 1a, Fullard and Yack 1993; Hoy et al. 1998; Stumpner and von Helversen 2001). While some species modified already-existing ears for the detection of ultrasound, numerous other insects that had previously lacked hearing evolved ultrasonic ears at this time (Miller and Surlykke 2001). For moths this acquired sensory ability may even have served as a starting point for the evolution of intraspecific acoustic communication. Within their auditory pathways, insects employ different neuronal substrates for the processing of intraspecific signals and sounds from predators (see below: categorical perception in crickets and parallel processing of information). Some species perform stream segregation within individual neurons by spectral and temporal cues (Schul and Sheridan 2006). Numerous species of grasshoppers have ears and hearing abilities, but produce no sound during mate attraction. For these species, hearing likely serves for predator detection only, and predation was the selection pressure under which ears evolved or were conserved (Riede 1987; Riede et al. 1990; Lehmann et al. 2007).

Host Finding

Hearing has evolved independently at least twice in parasitic flies in the context of finding hosts for their eggs. The performance of flies in localizing their host by its sound signal is most impressive, in view of their tiny ears located underneath the

head (Robert et al. 1996; Lakes-Harlan et al. 1999). With these tympanal ears flies can detect and localize not only the broadband sounds of bushcrickets and cicadas but also the pure tone signals emitted by crickets. For that goal flies possess sharply tuned hearing, as is evident from the sensitivity of their sensory receptors and auditory interneurons (Stumpner and Lakes-Harlan 1996; Robert and Hoy 1998; Robert and Göpfert 2002). Another example of host finding via auditory cues is a bloodsucking corethrellid fly that is attracted by frog calls (Bernal et al. 2006).

Two Types of Ears in Insects and their Constraints by Size and Signals

Generally, two principal types of ears are known: particle velocity receivers and sound pressure receivers (Fig. 1b–d, Michelsen 1979; Faure et al. 2009). (1) Particle velocity receivers exploit the vector component of sound particles close to the sound source. The antennae (arista) of flies, especially of *Drosophila* and mosquitoes, are a well-investigated model system for sound perception, auditory transduction, and active sensing (Robert and Göpfert 2002). Many insects, as well as arthropods in general, employ filiform hairs (located on the abdomen, cerci, legs, or other parts of the body, Fig. 1d) of different length to detect sounds of predators and prey (Barth 2002). A general property of particle velocity receivers is their limitation to lower frequency ranges (<500 Hz). Low frequency signals from small senders commonly have low amplitude and thus small range (e.g., wing movements by *Drosophila*), and the perception of particle velocity is then usually limited to the near field of the sender (a distance of a few wavelengths). Since the vector component of sound is perceived, these ears also provide directional information (Michelsen 1979; Faure et al. 2009). Their sensitivity matches or even surpasses that of tympanal ears (Robert and Göpfert 2002). (2) The perception of sound pressure is mediated by tympanal ears and follows the same principles as in vertebrates including humans (Fig. 1b, c, Montealegre et al. 2012). Tympanal ears in insects arose from the cuticular surface of their exoskeleton under which large air sacs derived from tracheal tubes, the respiratory

system of insects, were located. Since insects possess an abundance of mechanosensory proprioceptors for monitoring the strain and movement of their cuticle, auditory organs were prone to evolve from chordotonal organs in almost any part of the body (e.g., the legs, thorax, abdomen, and wings, Fig. 1a, Fullard and Yack 1993; van Staaden and Römer 1998). Tympana are usually small, and the sensitivity of the ears often extends into the ultrasonic frequency range. Sound localization via tympanal ears in larger vertebrates (Fig. 1b) requires the computation of interaural intensity and time differences as pressure receivers do not respond to the vector component of sound (Brown 1994; Yost 2000). Due to the small size of insects, intensity differences and in particular interaural time differences are too small to be exploited directly. Insects circumvent this problem by using tympanic *pressure difference* receivers, in which an internal connection by tracheal tubes exists between both ears (Fig. 1c). Small frogs, lizards, and birds face similar problems and also have developed pressure difference receivers. In these ears, the vibration amplitude of the tympanum is determined not only by the sound pressure at the outer side but also by the sound traveling through the body to the inside of the tympanum (Autrum 1942). The resulting pressure difference between the inside and outside will then determine the tympanal vibration. The amplitude of these vibrations depends on sound direction, because the phase angle of a given sound frequency at both sides of the tympanum is also dependent on the direction of the incident sound wave (Michelsen et al. 1994).

Themes of Auditory Processing in Insects

A major challenge in summarizing the capacities for auditory processing of insects results from the overwhelming diversity of hearing species, of functional ears, and of the different designs of auditory pathways. The subchapters below therefore give only a brief overview of the computational capabilities of insects for different tasks and under different constraints.

For auditory processing, insects exploit numerous general principles of sensory processing that are well known from other modalities and from

vertebrates, including mammals. Among these are the capacity for sound frequency analysis by a traveling wave, tonotopic representations and formation of internal neuronal maps, parallel processing of information, the timing and balance of excitation and inhibition for feature extraction, lateral and contralateral inhibition for contrast enhancement, transformation of coding from a temporal code to a place code, burst coding, resonant properties of neurons, selective attention, and even stream segregation.

However, insects face constraints on the computational power provided by their small brains. The concept of identified neurons, in which individual neurons could be identified by their morphology and physiology, arose from neurobiological research in insects and other arthropods (Huber and Markl 1983). Computations performed by thousands of neurons in mammals may find their counterpart in a single identifiable neuron of an insect, which illustrates an impressive compression of function (e.g., contralateral inhibition for directional hearing is mediated by the lateral superior olive in mammals and by a single local interneuron, ON1, in crickets and bushcrickets (Grothe 2000; Selverston et al. 1985; Römer and Krusch 2000).

Notably, the processing and coding capacity of insect nervous systems is restricted to relevant tasks. Peripheral filters and computations for instance aid in reducing the required processing power. Therefore, the ears of insects and their auditory pathways are by no means all-purpose devices, and processing is rather specific to function. Examples include crickets that distinguish only 2 categories of sound (mate signals and predators, Hoy 1989) and the tympanic ear of a moth that is equipped with only 2 sensory cells for bat detection (Boyan and Fullard 1988). Generally, insects also employ simple algorithms for processing at the cost of acuity, for example, by computing acoustic hemispheres rather than localizing the angle of a sound source (von Helversen 1997; Römer and Krusch 2000). Nevertheless, insects are by no means imprecise. At least in some species their performance for temporal resolution in a gap detection task has a precision in the millisecond range, rivaling that

of humans (von Helversen 1972; Prinz and Ronacher 2002).

Basic Steps of Auditory Processing: Transduction and Information Coding by Sensory Neurons

In both tympanal ears and particle velocity receivers, sound induces the vibration of a structure (a thin membrane or a lever on a flexible pivot, Michelsen 1979; Robert and Göpfert 2002). The mechanical oscillation distorts the dendrite of a scolopidial cell, which is attached to the lever, the tympanum, or a tracheal tube (Fig. 1e1, e2). This distortion opens mechanosensitive ion channels, which are not yet fully characterized, and the resulting current transduces the movement into a change of the cell's membrane potential (Fig. 1e3; Gollisch and Herz 2005). Evidently, the membrane potential of sensory neurons cannot follow the fast vibrations of the tympanal membrane in the kilohertz range; rather, the membrane potential depends on the instantaneous sound pressure level. Similar to vertebrates, frequency discrimination occurs according to a frequency-place transformation (Montealegre et al. 2012). Either in the sensory neuron itself or in a downstream neuron, the membrane depolarization is then translated into a series of action potentials, a spike train, which encodes the sound envelope by modulations of the spike rate (Fig. 1e4). Spike rates of auditory afferents can be high, up to 400 Hz or more (Römer 1976).

Although insect and vertebrate ears obviously evolved independently, and the insect mechanoreceptors (scolopidia) differ from auditory hair cells of vertebrates, in the last decade many unexpected commonalities were detected. Recently, active processes were found in insect ears that serve to attain and adjust their formidable sensitivity, similar to the function of outer hair cells in the mammalian cochlea (Robert and Göpfert 2002; Nadrowski et al. 2011). In both locusts and bushcrickets, traveling waves were observed to play an essential role in frequency discrimination. As in the mammalian cochlea, traveling

waves exhibit peaks at different locations, depending on sound frequency (Windmill et al. 2005; Hummel et al. 2011; Montealegre et al. 2012). In addition, in central projections of auditory afferents, there is a tonotopic representation of frequencies (Römer 1983; Römer et al. 1988; Stumpner 1996; Stölting and Stumpner 1998). Finally, the development of the auditory organ of *Drosophila* depends on similar genes, e.g., of the atonal family, as the vertebrate ear (Senthilan et al. 2012).

Although the *temporal* resolution of insect ears can match that of vertebrates in some respects (see below), the *frequency resolution* of insects is generally inferior to that of vertebrates. In crickets we find a kind of “categorical response,” by which the frequency scale is segmented into two parts: sound pulses with carrier frequencies above 15–20 kHz (up to 100 kHz) evoke an avoidance response, whereas sound pulses with frequencies between 3 and 10 kHz are attractive and evoke a positive steering response when flying (Moiseff et al. 1978; Hoy 1989). Remarkably, however, in an interneuron of a bushcricket, a sharpening of the broader frequency tuning of auditory receptors by frequency-dependent “lateral” inhibition similar to vertebrates has been observed (Stumpner 1997). The sharpness of frequency tuning of auditory neurons is commonly described by the $Q_{10\text{dB}}$ score. This gives the ratio between the characteristic frequency (i.e., the frequency of the neuron's lowest threshold) and the width of the tuning curve 10 dB above the lowest threshold. Typical values for insects are between 0.5 and 2.5 and only rarely extend to 3.5 (Hennig et al. 2004), whereas in vertebrates, we find much higher values, between 1 and 25 (and up to 400 in the acoustic foveae of bats, Suga et al. 1997).

The dependency of spike rate on sound intensity is commonly depicted by the f-I curve (firing rate vs. intensity, also rate-intensity curve; Fig. 1f, g). The dynamic range between threshold and saturation indicates the region of discriminable sound intensities. The steepness of the f-I curve determines how well small sound pressure differences can be discriminated – which is important for directional hearing and when fine modulation details of a signal have to be assessed (compare

Fig. 1f, g). A steep f-I curve, however, has the disadvantage that it covers only a small part of the relevant sound intensity range which may extend to 100–120 dB SPL (Fig. 1f). (Note that the dB SPL scale is a logarithmic scale that expresses sound pressure relative to 20 μ Pa; a 100 dB sound has a 10^5 larger sound pressure compared to the human hearing threshold at 1 kHz.) As in other sensory systems, the intensity range problem may be solved by adaptation, by which the f-I curve can be adjusted to the average ambient sound pressure levels (Benda and Herz 2003; Benda and Hennig 2008). Spike frequency adaptation as early as the level of sensory neurons helps to attain a certain degree of intensity invariance that is important for object identification and behavioral decisions (Benda and Hennig 2008). However, in different neuron types we may find different biophysical realizations, ranging from cell-intrinsic spike-triggered adaptation currents to inhibitory inputs and presynaptic adaptation mechanisms (Gollisch and Herz 2004; Hildebrandt et al. 2009). A complementary way to cope with the large range of encountered sound intensities may be a kind of “range fractionation.” In locusts and bushcrickets, for example, we find auditory receptors with a rather limited dynamic range of 20–30 dB. Since different receptors exhibit a similarly broad frequency tuning but very different thresholds, intensity discrimination is possible over a broad range (Römer 1976; Römer et al. 1998).

Obviously, the spike trains of sensory neurons are the only information any central nervous system has about events in the external world. In other words, the brain has to infer the structure of the outer world from the spike trains arriving from various sense organs. The very successful stimulus reconstruction methods seek to understand signal processing from the viewpoint of the central nervous system and to infer information about an external stimulus from the spike trains of sensory neurons (Rieke et al. 1997). The basic idea is to reconstruct the stimulus envelope from spike trains that have been recorded in response to that stimulus. By this procedure we can estimate how much information the CNS can obtain about a sensory stimulus and what aspects

of the stimulus are lost. For example, from the spike trains of the locusts’ auditory afferents, stimuli with large modulation amplitudes can be reconstructed more accurately than stimuli with small modulation depths (Machens et al. 2001). Remarkably, grasshopper songs seem to be matched to this feature of the receiver’s auditory periphery. This investigation has further shown that in the very periphery of the auditory pathway, a single sensory neuron transmits a high amount of information, up to 180 bits/s (Machens et al. 2001).

Processing of Signal Envelopes within the Auditory Pathway

Temporal Resolution and Temporal Integration

The communication signals of many species contain fast amplitude modulations that are evaluated by females to assess the attractiveness of potential mates. Hence, we must ask whether there are neuronal constraints that determine the behavioral *limits of temporal resolution*. Two widely used paradigms to investigate these limits are modulation transfer functions (MTF) and gap detection (for reviews see Green 1985; de Boer 1985; Michelsen 1985; Viemeister and Plack 1993; Joris et al. 2004). In the MTF paradigm either random modulations in a certain frequency band or sine wave modulations are used. The latter paradigm can be applied in neurophysiological as well as in behavioral experiments. Stimuli with appropriate carrier frequencies are presented that exhibit sinusoidal amplitude modulations of different frequencies and reveal what range of modulation frequencies the system is able to represent, and if there are specific modulation frequencies to which a system responds particularly well, see Fig. 3a for an example. The black dots in this diagram show the attraction of cricket females to a 4.5 kHz tone that was amplitude modulated at frequencies between 1 and 50 Hz; two regions of enhanced attractiveness around 3 and 30 Hz are obvious (Wendler 1989; Hennig 2009). In spike train recordings one can determine the average spike count

Auditory Processing in Insects, Fig. 3 Temporal resolution of amplitude modulations in grasshoppers and crickets. **(a)** Behavioral modulation transfer function of crickets (filled symbols, stimuli as in 1 and 2 at right). Best responses are obtained if lower and higher modulation frequencies for pulse and chirp (i.e., groups of pulses) are combined in one stimulus as in patterns 3 and 4 at right (open symbols). **(b)** Gap detection in a grasshopper measured in behavioral experiments (black curve) and neuronal response (red curve, AN4). **(c)** Response of the AN4 neuron to uninterrupted and gap containing sound

syllables. This neuron responds to sound onset first with a deep inhibition, an IPSP (arrows), followed by excitation and spikes (upper traces). In the interrupted stimuli, each onset after a gap triggers the IPSP anew which leads to an effective suppression of spiking (lower traces, adapted from Ronacher & Stumpner 1988). **(d)** Gap detection in crickets (behavioral data) ((a) From Hennig 2009; (b) modified from von Helversen 1972 and Franz and Ronacher 2002; (c) modified from Ronacher and Stumpner 1988; and (d) from Schneider and Hennig 2012, with permission)

(rate, r-MTF) or evaluate how well the spikes are locked to a period of the stimulus envelope (temporal, t-MTF). r-MTF reveals a neuron's filter properties, e.g., high-pass, low-pass, band-pass, or band-reject features for sound pulse rates. The t-MTF, in contrast, indicates how well fast modulations can be resolved by a neuron. One should be aware, though, that the construction principle of MTFs is based on a large amount of averaging, and therefore, the information provided by single spike trains may be lower

than that suggested by a MTF (Wohlgemuth et al. 2011).

The second paradigm, gap detection, has been applied in behavioral experiments to grasshoppers and crickets (von Helversen 1972; von Helversen and von Helversen 1997; Schneider and Hennig 2012). Grasshoppers detect gaps of 2–3 ms duration and in this respect are not inferior to vertebrates (Fig. 3b, Prinz and Ronacher 2002). This high resolution of gaps seems to be mediated by the specific interactions between inhibition and

excitation in one identified interneuron (Fig. 3c; Ronacher and Stumpner 1988). The temporal resolution of cricket ears is lower compared to grasshoppers; minimal detectable gap widths are between 6 and 8 ms (Fig. 3d, Schneider and Hennig 2012). One reason for this may stem from the males' sound production system: cricket songs are produced by a resonant mechanism which precludes very fast amplitude changes (Bennet-Clark 1998). Hence, on the receiver's side there is no need to push the temporal resolution to extremes. In addition, compared to broadband signals, which are typical in many grasshoppers and bushcrickets, pure tone signals, such as those produced by many crickets, tend to be more strongly affected by random amplitude fluctuations when traveling through the habitat, which also sets limits for temporal resolution (Römer and Lewald 1992).

Temporal integration refers to the *time-intensity trading* paradigm. In these experiments the minimal audible threshold was found to depend on the duration of the stimuli used. To detect very short stimuli, e.g., of 5 ms duration, higher sound intensities are necessary than for longer, e.g., 100 ms, stimuli. The product of sound intensity and stimulus duration determines the threshold up to durations around 200–300 ms, whereas for longer stimuli, the threshold stays constant (Green 1985). Hence, we are confronted with an apparent discrepancy, the temporal integration-resolution paradox (de Boer 1985): gap detection and MTF paradigms yield time constants in the order of 1–6 ms, whereas from the time-intensity trading paradigm, we are left with time constants in the range of 150–300 ms (for a discussion of this paradox and possible solutions, see de Boer 1985; Viemeister and Wakefield 1991; Tougaard 1998; Pohl et al. 2013).

Transformation of Coding Along the Auditory Pathway

In insects and other arthropods, many neurons can be uniquely identified on the basis of their characteristic morphology. The peripheral stage of a grasshopper's auditory pathway comprises sensory neurons (afferents), local neurons whose processes are confined to the thoracic ganglia, and

ascending neurons, whose axons reach the brain. Present knowledge indicates that this corresponds to a feedforward network (Fig. 4a, Vogel et al. 2005; Vogel and Ronacher 2007).

Auditory afferents exhibit high firing rates, up to several hundred Hertz (Fig. 4c). Their tonic spike responses represent the amplitude modulation patterns of auditory stimuli by a modulation of the firing rate. The variability of their responses is rather low (see Fig. 4d, e). The precise responses of sensory neurons allow for a good discrimination and classification of auditory stimulus ensembles (Machens et al. 2003; Wohlgemuth and Ronacher 2007).

Along the auditory pathway the maximal spike rates decrease, whereas the spike train variability increases (both spike count and inter-spike-interval variability, Fig. 4c–e). In accordance with the larger variability of higher-order neurons, the temporal resolution and the classification success for similar stimuli decrease markedly among the ascending neurons. At the level of afferents and among primary-like local neurons, we find a high classification success that depends almost exclusively on the timing of spikes. In contrast, among ascending neurons the classification success based on a single neuron's responses decreases, and spike count differences between stimuli become more important (Wohlgemuth and Ronacher 2007). Among ascending neurons, the information appears to be distributed among several neurons and to be represented as a labeled-line population code (Clemens et al. 2011, 2012). A similar reduction in spike rates from ascending to brain neurons is observed within the auditory pathways of crickets (Schildberger 1984; Kostarakos and Hedwig 2012).

Central Processing in the Frequency or Time Domain?

With Fourier analysis, a signal's temporal structure can be broken down into sine waves, each having a particular amplitude and phase (see, e.g., Yost 2000). If both the resulting spectra for amplitude and phase are known, the original signal can be fully reconstructed. Therefore, there are two principal means of processing a periodic signal: an analysis in the frequency domain, i.e., of the

Auditory Processing in Insects, Fig. 4 Transformation of coding along the auditory pathway. (a) Scheme of a grasshopper's auditory pathway (AFF auditory afferents, LN local neurons, AN neurons whose axons ascend to the brain). Numbers indicate approximate numbers of neurons at the respective levels. (b) Response (numbers of action potentials at right) of an ascending neuron (AN1) to five presentations of an identical stimulus. (c) Maximal spike

rates at different processing levels. (d) Variability of interspike intervals (CV variation coefficient). (e) Variability of spike count (expressed as Fano factor FF). amplitude spectrum without phase and thus without temporal information, and an analysis in the time domain by the computation of temporal parameters such as durations and periods of events. For instance, the processing of the sound carrier by a traveling wave is equivalent to the computation of an amplitude spectrum for a frequency analysis.

The envelopes of the communication signals of many insect species have a highly regular and repetitive structure and consist of a series of stereotyped subunits. Remarkably, several experiments have shown that crickets and grasshoppers accept song signals with randomized or shuffled patterns as conspecific (Fig. 5, Pollack and Hoy 1979; von Helversen and von Helversen 1998; Schmidt et al. 2008). This suggested that central processing may be restricted to the frequency domain and serve to compute an amplitude spectrum of the song envelope. A crucial experiment

to determine whether a signal is processed in the frequency or time domain is to present reversed or inverted versions of an attractive signal (see Fig. 5e, f). Inverted variants exhibit the same amplitude spectrum as the original but differ in their phase components and thus temporal qualities. If such modified song models show the same attractiveness as the original, a spectral analysis of the signal envelope is very likely as opposed to temporal processing. However, evidence from experiments as shown in Fig. 5e, f and others revealed large differences in attractiveness which suggests that insects process the amplitude modulations of sound stimuli in the time domain (von Helversen and von Helversen 1998; Schmidt et al. 2008; Hennig 2009).

Global Algorithms of Coding

Which global algorithms of coding are implemented in the auditory pathways of insects

Auditory Processing in Insects, Fig. 5 Regular song patterns and the importance of temporal order for recognition. (a) Regular calling song of the cricket *Teleogryllus oceanicus*. (b–d) Song models (top) for tests of preference of females and relative frequency of different pulse intervals (bottom). Note the differences in the interval distributions between (b, c, and d). (b) Song model of *T. oceanicus*. (c) Shuffled song model with the same relative frequency of pulse intervals as in (a). (d) Song model of *T. commodus*. Song models of (b) and (c) are attractive for females of *T. oceanicus*, although the temporal order in

c is randomized. The song pattern in (d) from the sibling species is not attractive. Although this experiment suggested central processing of the signal envelope in the frequency domain, the bulk of experimental evidence demonstrates processing in the time domain by crickets and other Insects. (e, f) Envelopes of reversed song models for behavioral tests with grasshoppers. The pattern in (e) is very attractive, but the reversed version in (f) is rejected (von Helversen and von Helversen 1998) ((a–d) From Pollack and Hoy 1979 with permission; (e, f) from von Helversen and von Helversen 1998, with permission)

to achieve the goals of hearing (see Overview and Background)? In the context of acoustic communication as well as predator avoidance, insects have to recognize specific sound signals for which they possess an innate, internal representation. Presently there is no evidence for a maplike neural representation of specific features in the auditory pathways of insects, except for the tonotopic frequency maps in the periphery (Hildebrandt 2014). For predator avoidance ultrasonic cues and the detection of strong onsets as a typical effect of intense bat calls appear to be most important. Burst coding in the auditory pathways of crickets and grasshoppers shows how onsets are detected (see below, Marsat and Pollack 2006; Creutzig et al. 2009; see also Krahe and Gabbiani 2004). For the recognition of conspecific signals, several global schemes were proposed:

autocorrelation, cross-correlation with a template, or combinations of high-, low-, and band-pass filters. All these schemes are derived from Fourier transformation and represent mathematical and technical solutions, for which evidence from several investigations exists (Schildberger 1994; Weber and Thorson 1989; Hennig 2003). However, only a few studies have been able to reproduce the preferences exhibited by female insects over a wider range of signals (see Fig. 6a–c for response profiles from several species of crickets, bushcrickets, and grasshoppers upon presentation of stereotyped sound patterns composed of subunits built by regular pulses and pauses (von Helversen and von Helversen 1994)). In a recent alternative approach, the recognition of sound signals was examined using linear-nonlinear (LN) models adapted from computational

Auditory Processing in Insects, Fig. 6 Preference profiles of female insects for song signals and LN models. (**a–c**) Preference profiles for song signals in the time domain by crickets, bush crickets, and grasshoppers (A: oce oceanicus, com commodus; B: cau caudata, can cantans, vir viridissima; C: br brunneus, big biguttulus, mo mollis). (**d–e**) LN models account for preference functions of the cricket *Gryllus bimaculatus*. (**d**) Two LN models (red, green) that predict the preferences for pulse patterns by female crickets (*G. bimaculatus*): linear filters (left panels)

and the respective nonlinearities (central panel) that predict behavioral responses of female crickets (right panel). Note that the duration of the linear filters is only 64 ms. The red dot in the right panel of (**d**) refers to the pattern in (**e**). (**e**) Output of the LN models (**d**) in response to a song model (upper trace). Response of the linear filters to the song model before (left panels) and after passing through the nonlinearity (right panels). The upper filter (red in **d** and **e**) responds like an onset detector; the lower filter resembles a Gabor-function and selectively responds to

neuroscience (Clemens and Hennig 2013; Clemens and Ronacher 2013). For crickets as well as grasshoppers, Gabor functions emerged as filters that responded best to particular subunit shapes common to the conspecific song signal (combinations of pulse and pause or pairs of pulses, Fig. 6d, e). Gabor functions (a sine wave multiplied with a Gaussian function) are well known from sensory pathways in vertebrates (visual, Daugman 1984; Simoncelli and Olshausen 2001; Priebe and Ferster 2012; auditory, Smith and Lewicki 2006). However, the most notable property of the proposed LN model was the independence of the computation from the exact timing of occurrence of the template within a larger time window. Therefore, this LN-model approach offers an elegant solution to the attractiveness of shuffled and irregular song signals (see Fig. 5 and subchapter: processing in the frequency or time domain). Small modifications of Gabor functions are capable of reproducing response profiles known from several species of insects (Fig. 6a–c, Clemens and Hennig 2013). Although these filters by default describe the output of the whole recognition system, present evidence suggests that certain identified neurons in crickets may represent a neuronal correlate of specific LN features (compare Fig. 6e–g, Zorović and Hedwig 2011; Kostarakos and Hedwig 2012; Clemens and Hennig 2013).

Local Mechanisms of Coding

For insects there exist several prominent examples of how global algorithms of coding are at least in part implemented by identified neurons. For instance, the detection of bat predators by crickets is mediated by a specific auditory neuron (AN2), whose bursting is crucial for a behavioral response (Fig. 7, Nolen and Hoy 1984; Marsat and Pollack 2006). Similarly, the AN12 in

grasshoppers codes for a specific song feature by bursts (Creutzig et al. 2009). Specific combinations of excitation and inhibition account for feature extraction in grasshoppers (gap detection by AN4; Ronacher and Stumpner 1988 – see temporal resolution) and serve as a basis for pulse rate detection by the identified neuron B-LI4 in crickets (Kostarakos and Hedwig 2012). Similarly, resonant properties within the auditory pathway of bushcrickets mediate the detection of specific pulse rates and can be modeled as a property of single neurons (Bush and Schul 2006; Webb et al. 2007). Short time constants of single identified neurons allow them to act as feature detectors for ultrasonic pulses in the auditory pathway of moths (Boyan and Fullard 1988).

Processing under the Constraints of Noise: A Twofold Problem

Noise poses unavoidable problems for all sensory systems. There are two classes of noise, external and internal. Various types of external noise influence sound waves on their way from sender to receiver. Hence, as a rule, receivers have to cope with signals that are masked and degraded in their temporal structure (e.g., Michelsen and Larsen 1983; Römer et al. 1989; Römer 2001; Schmidt et al. 2011; see also Brumm and Slabbekoorn 2005; Wiley 2006).

Crickets with their pure tone songs have found a solution to reduce the impact of external noise. The females' hearing system is tuned to the carrier frequency of male songs and becomes increasingly less sensitive to frequencies farther from the carrier frequency (Fig. 2g, h). The sharpness of the tuning curve may depend on ecological conditions (Schmidt et al. 2011). A cricket species (*Paroecanthus podagrosus*) living in very noisy tropical rainforests exhibits an exceptionally narrow tuning ($Q_{10dB} \sim 4$) that allows for an efficient

Auditory Processing in Insects, Fig. 6 (continued) pairs of pulses (green in d and e). (f–g) The response pattern of an auditory interneuron in the cricket brain resembles the output of the onset detector (red in d, e). The neuronal discharges in (g) illustrate onset responses to

sound patterns with different pulse rates ((a–c) From Hennig et al. 2004; (d, e) modified from Clemens and Hennig 2013; and (f, g) from Zorović and Hedwig 2011, with permission)

Auditory Processing in Insects, Fig. 7 Burst coding by an identified interneuron (AN2) and avoidance behavior in crickets to bat like stimuli. (a) Bursts in AN2 in response to amplitude-modulated stimuli (carrier frequency: 30 kHz); burst spikes are marked as *black* dots in raster plot. (b) Response of AN2 to a sound stimulus (as in a) and

behavioral response (*bottom trace*: abdominal movements away from the sound source). (c) Amplitude of abdominal movements after isolated action potentials (*gray*) or bursts (*black*). Positive values indicate abdomen flexion away from the sound source (From Marsat and Pollack 2006, with permission)

Auditory Processing in Insects, Fig. 8 Processing under the constraints of noise: a twofold problem. (a) Song of a tropical cricket *Paroecanthus podagrosus* (*upper trace*). Lower traces. 1: Song envelope. 2: Song envelope under ambient noise levels as recorded in the habitat. 3: Song plus noise less efficiently filtered with the broader tuning curve of a European cricket (*Gryllus bimaculatus*). 4: Song plus noise filtered with the narrow tuning curve of *P. podagrosus*, compare Fig. 2h (Adapted from Schmidt et al. 2011). (b) Effects of intrinsic noise and external signal degradation on spike train dissimilarities of

three representative neurons, assessed with the van Rossum metric and corrected for spike rate differences. The *black* arrow at “orig” indicates the average spike train distance found for repeated presentation of the original song pattern, i.e., the result of trial-to-trial variability. The *open* arrow indicates the additional distance caused by the most strongly degraded signal. AFF sensory neuron, TN1, and SN1 two primary-like local neurons. ((a) Modified from Schmidt et al. 2011. (b) Modified from Neuhofer et al. 2011 and Ronacher 2013, with permission)

suppression of ambient noise (Figs. 2h, 8a). Thus, in this species we find a narrow peripheral filter that is perfectly matched to the carrier frequency of conspecific signals and dismisses signals from other species, at the expense of reducing the range of perceivable sounds (Fig. 8a). Many bushcrickets use broadband communication signals which yield a twofold advantage. First,

broadband signals are less likely to be degraded in the biotope compared to narrowband signals (Michelsen and Larsen 1983; Römer and Lewald 1992). In addition, the receiver’s nervous system can compare the neuronal signals from differently tuned auditory receptors and thereby reduce intrinsic neuronal noise (see below). Note that the hearing systems of vertebrates (mammals,

owls) also use broadband signals to reduce noise or to resolve localization ambiguities (Konishi 1990).

In addition to external noise, auditory systems face a second noise problem. Neuronal signals are inherently noisy due to the stochastic opening and closing of ion channels. This *intrinsic noise* becomes evident as trial-to-trial variability of spike trains in response to repeated presentations of an identical stimulus (see Fig. 4b). Animals with a large nervous system may alleviate this problem by averaging responses from many neurons with similar properties. However, due to size constraints insects probably cannot afford this solution. Under some conditions noise may play a beneficial role and improve neural computations, for example, by stochastic resonance (for review see McDonnell and Ward 2011).

To quantify the trial-to-trial variability or to compare neuronal responses to different stimuli, one can apply a *spike train metric* (see, e.g., van Rossum 2001). This metric describes the similarity of two spike trains by a single number, which is in line with our intuition of distance: small values indicate high similarity. The metric uses an adjustable parameter to take into account both differences in the spike count as well as in the timing of spikes. This metric approach was used to determine the relative impacts of external and intrinsic noise on the encoding of envelope-degraded stimuli by auditory neurons of grasshoppers (Neuhofer et al. 2011). Unexpectedly, the contribution of external signal degradation to the overall spike train distances was low: even for the highest degradation level, its amount did not exceed that of intrinsic noise (Fig. 8b).

As long as rather different signals have to be analyzed, neuronal noise may not be a very serious problem. However, with communication signals that serve to attract mates, it will be necessary to discriminate between similar signals and to detect small deviations from a species-specific pattern. This is especially the case if quality cues from the sound signals of potential partners are to be extracted. Remarkably enough, the spike trains of even a single

auditory afferent allow for an almost perfect discrimination of songs of different males of one species (Machens et al. 2003). At higher stages in the auditory pathway, however, the discrimination deteriorates and intrinsic noise cannot be neglected as a limiting factor. Grasshoppers appear to have circumvented this intrinsic noise problem by changing the coding scheme at a rather peripheral stage of processing (see Fig. 4a): among the ascending neurons information is distributed according to a labeled-line code (Clemens et al. 2011, 2012; see also Clemens and Ronacher 2013).

Directional Hearing

The biophysical qualities of the pressure difference receivers equip the ears of insects with a directional dependence of the vibrational amplitudes of their tympana (Michelsen 1998). Sensory neurons reflect this dependence in spike numbers, and for some species, this difference in response strength is also translated into timing differences (enhanced by ramps Krahe and Ronacher 1993; Ronacher and Krahe 2000). The contrast in response magnitude of sensory neurons for left and right differences is enlarged by contralateral inhibition from local interneurons (ON neurons in crickets, Selverston et al. 1985; bushcrickets, Römer and Krusch 2000; LN in grasshoppers, Marquart 1985). The representation of sound from one side is therefore enhanced, because the responses to sound from the opposite side are suppressed, and this takes place already at early levels of auditory processing of sound direction, usually at the first synapse after sensory receptors. This mechanism of contralateral inhibition in auditory pathways transforms the acoustic environment of insects into acoustic hemispheres. These hemispheres enable a rather accurate distinction of left and right sound signals at the cost of accuracy in determining the angle of the sound source (lateralization in grasshoppers, von Helversen and Rheinlaender 1988). A corollary of the computation of acoustic hemispheres is that sound signals are selectively represented on one side of the insect or the other. This computation resembles the phenomenon of selective attention

Auditory Processing in Insects, Fig. 9 Acoustic hemispheres and selective representation of sound patterns in bush crickets. (a, b) Left and right specimens of the local interneuron ON1 were recorded simultaneously, while different sound signals (pattern 1 and 2) were presented from

either side. (c) Both interneurons selectively represent only the sound pattern from one side (inset: experimental arrangement, correlation coefficient of the spike train with the sound pattern as a measure for copying fidelity) (From Römer and Krusch 2000, with permission)

(Pollack 1988) and allows insects to discriminate sound sources in much the same way as the cocktail party effect well known from humans (Fig. 9, Römer and Krusch 2000). Notably, contralateral inhibition and acoustic hemispheres can exert a considerable influence on mate choice as females of bushcrickets prefer males that take a leader role among singing males, since the representation of the song signal of a follower is suppressed in their auditory pathway (Hartbauer et al. 2005; Siegert et al. 2011). These local computations for enhanced directional responses can also affect the singing behavior of males and promote synchronization and thus chorusing among males (Greenfield and Roizen 1993; Greenfield 1994; Hartbauer et al. 2005). Due to the computational conflict between representation of sound pattern and sound source, grasshoppers split the sensory pathways for processing of cues for pattern and direction by parallel processing (von Helversen 1984; Ronacher et al. 1986). However, in the evolutionarily older communication systems of crickets and bushcrickets, serial processing of pattern and direction appears to prevail (Wendler 1989; Stabel et al. 1989; von Helversen and von Helversen 1995; Schul et al. 1998).

Conclusions

Auditory processing in insects is constrained by small body size and a relatively small number of neurons. Thus, the hearing capacities are focused on highly relevant tasks, such as predator detection, mate attraction, and, in some cases, eavesdropping on prey or host signals. Insect ears evolved from cuticular mechanosensory proprioceptors and may respond to different aspects of sound waves – particle velocity or sound pressure; ears can be found in almost any part of the body, and as a consequence, different neural structures are involved in auditory processing. In the auditory pathways, we find similar computational principles and transformations of sensory representations as in vertebrates, however, with an important difference: complex computations are often performed by single neurons or very small populations of identifiable neurons. This size constraint and the focus on a few relevant tasks facilitate experimental approaches.

Acknowledgments We want to thank the members of our lab who contributed to several of the cited studies. Special thanks are due to Dr. Michael Reichert who gave helpful advice on the English style and substantially improved the manuscript, as well as to an anonymous reviewer whom we owe many helpful suggestions.

Auditory Prosthesis

Johan H. M. Frijns and Jeroen J. Briaire
ENT Department, Leiden University Medical
Center, Leiden, The Netherlands

Synonyms

Bionic ear; Cochlear implant; Inner ear prosthesis

Definition

An auditory prosthesis is an implantable device used to (partially) restore the auditory function in people with a severe to profound hearing loss by electrically stimulating the auditory neural pathway. The cochlear implant, stimulating the auditory nerve from within the cochlea, is widely accepted as the standard rehabilitation device for this population. An auditory brain stem implant uses the same technology to stimulate the neurons of the cochlear nucleus in the brain stem and is used when the cochlea is not accessible (e.g., due to ossification after meningitis or severe hypoplasia) or the cause of deafness is found in the internal auditory canal (bilateral acoustic neuroma, aplasia of the auditory nerve).

Detailed Description

Background

Due to their reduced oral communication skills, severe to profoundly deaf people are restricted in their social functioning. Since the pioneering work of Djourno and Eyries (1957) and House

in the 1970s of the last century (House and Urban 1973), it has become possible to restore some of the hearing functions through direct electrical stimulation of the auditory nerve. Currently used cochlear implants utilize electrode arrays with 12–22 contacts on a Silastic carrier that are most commonly inserted into the scala tympani through either the round window membrane or a drilled cochleostomy in its vicinity. This allows taking advantage of the tonotopic organization of the cochlea and the auditory nerve, where the high frequencies are encoded at the basal end, while the low frequencies are encoded more to the apical end (Ruggero 2009). In this way, each electrode contact of a multichannel implant aims to stimulate a different neural population, which physiologically encodes a certain pitch as determined by its intracochlear position. With current devices, however, the wish to encode all spectral information relevant for speech understanding leads to a mismatch between their tonotopic map and the physiological one.

In 1984, the first cochlear implant obtained FDA approval for implantation in adults. This was followed by an NIH consensus in 1995 stating that cochlear implantation is a proven and effective rehabilitation method for deaf children and deaf adults. Today, over 188,000 people have received a cochlear implant (<http://report.nih.gov/nihfactsheets/ViewFactSheet.aspx?csid=83>). Initially, the implants provided a signal function and an aid in lipreading. Nowadays, driven by improved electronics and speech coding strategies, better electrodes and changes in inclusion criteria, the majority of the recipients achieves open set speech understanding and is able to use the telephone, although this still requires an intensive rehabilitation process (see Fig. 1).

Components and Signal Processing of Multichannel Implants

A cochlear implant consists of an external part and an internal part, as shown in Fig. 2.

An otolaryngologist surgically implants the internal part (the so-called receiver-stimulator package with the electrode array) under general

anesthesia; the externally worn speech processor (body worn or behind the ear) is connected after several weeks of wound healing. The speech

processor captures the incoming sound and, after preprocessing (typically noise cancellation and amplitude compression), encodes it into frequency-specific electrical information to be sent to the individual electrode contacts in the cochlea.

The speech coding strategies used in all current implants are extensions of the continuous interleaved sampling (CIS) strategy (Wilson et al. 1991). This strategy tries to avoid electrical interaction between neighboring electrode contacts by stimulating all contacts in a sequential mode rather than simultaneously. A digital filter bank is used to process the signal into separate frequency bands. Next, the envelope of each band, determined by rectification and low-pass filtering of the signal, is used to set the amplitude of a sequence of nonsimultaneous pulses on the implanted electrode contacts. The rate of stimulation is determined by the device brand and by the patient's performance, but typically ranges between 400 pulses/s and 4000 pulses/s per channel.

Auditory Prosthesis, Fig. 1 Performance over the first year of cochlear implant use of 70 consecutive patients implanted with a HiRes90K implant with a HiFocus 1 J electrode array (Advanced Bionics, Valencia, CA). The bars represent the percentage of correctly understood Dutch monosyllabic (CVC) words, presented from CD (65 dB SPL, free-field in quiet). The preoperative data were obtained with the best-fitted hearing aid

Auditory Prosthesis, Fig. 2 The components of a cochlear implant with a behind-the-ear speech processor. (Courtesy of Advanced Bionics)

Both the encoded stimulation pattern and the energy are transmitted to the implanted receiver-stimulator package through an RF-link. The external and internal coils for this RF-link are kept aligned with magnets in the center of both coils. The signal is picked up by the electronics in the receiver-stimulator package, which in turn delivers electrical pulses to the auditory nerve fibers via electrode contacts in the electrode array.

Modern cochlear implants also have back telemetry, allowing to record electrically evoked compound action potentials (eCAPs) of the auditory nerve via the implanted electrode array.

Computational Modeling

To provide more insight in the fundamentals of functional electrical stimulation of the auditory nerve, computational models have been developed. This involves stimulating not only the response of a nerve fiber to an externally applied potential field but also the calculation of this potential distribution from the currents on the stimulating electrodes. This is especially intricate in the case of cochlear implants due to the complex geometry of the inner ear.

Electrical Volume Conduction in the Cochlea

An analytic solution of such a 3D volume conduction problem is restricted to geometries that are much simpler than the cochlea, and many theoretical models on the (actually three-dimensional) potential pattern set up in the cochlea by the stimulating current sources assumed an exponential decay of current from its source to the nerve fibers along the cochlea, modeled in one dimension (O’Leary et al. 1985), while other analytical approaches assume a simplified unrolled anatomy (Goldwyn et al. 2010). Suessermann and Spelman (1993) used an electrical network as a practical representation of the electro-anatomy of the cochlea.

Numerical methods nowadays, however, allow to incorporate much more detailed (electro-) anatomical information (including the shape and

position of the electrode array) and sometimes even allow for patient-specific modeling on the basis of CT-scans (Carlyon et al. 2010). The numerical methods that have been used include the finite difference method (Whiten 2007), the finite element method (Rattay et al. 2001; Hanekom 2001), and the boundary element method, also known as the integral equation method (Frijns et al. 2001).

Simulating the Auditory Nerve Fiber Responses

Colombo and Parkins (1987) were the first to develop a cable model of the mammalian auditory nerve neuron based on the classical work on amphibian nerve fibers of Frankenhäuser and Huxley (1964). In order to fine tune the model to represent physiological data obtained from single auditory nerve fiber experiments in squirrel monkeys, they had to adapt the modeled nerve fiber’s anatomy significantly. Motz and Rattay (1986) used a single-node model with the Hodgkin and Huxley model of unmyelinated squid giant axon membrane (► “Hodgkin-Huxley Model”) to investigate the time structure of the response of the (myelinated!) auditory nerve to electrical stimuli. The gSEF model (Frijns et al. 1995) is a nonlinear cable model, which represents essential mammalian nerve fiber properties, including spike duration and conduction velocity, refractory behavior, and repetitive firing, better than previous models and can deal with arbitrary stimulus wave forms. It is based upon voltage clamp measurements in rat and cat motor nerve fibers at mammalian body temperature performed by Schwarz and Eikhof (1987). The gSEF model and its variants have, in conjunction with electrical volume conduction models, been used not only to predict which (intact or degenerated) fibers are excited by specific patterns of electrical stimulation (Smit et al. 2010; Frijns et al. 2009a, 2011) or to explain the results obtained with psychophysical experiments (Carlyon et al. 2010; Snel-Bongers et al. 2013) but also to calculate the eCAP produced on the basis of predicted single fiber action potentials (Briaire and Frijns 2005; Westen et al. 2011).

Auditory Prosthesis, Fig. 3 (a) The structure of a 3D volume conduction model of the implanted human cochlea (as developed at the Leiden University Medical Center), including the auditory nerve (in yellow) and a realistic

representation of the electrode array in the scala tympani. (b) The potential distribution in the neural compartment due to monopolar stimulation

The abovementioned neural models have in common that they are deterministic in the way they treat the neural membrane responses. If the focus of research is more on the effect of high stimulation rates or on repetitive near-threshold stimulation, stochastic models come into play. Most models of this type are single-node threshold models (Bruce et al. 1999), while cable models (Rubinstein et al. 1999; Imennov and Rubinstein 2009), although computationally very intensive and requiring supercomputers, can give insight in more complex stimulation patterns.

Integrated Use of Volume Conduction and Neural Models: State of the Art

While in the early days of cochlear implantation all insights in the mechanisms underlying their function had to come either from clinical practice and associated psychophysics or from animal experiments, nowadays sophisticated computational models exist, which integrate a model of electrical volume conduction in the cochlea with active neural models. Such models can not only be used to explain effects of current and future electrode designs and stimulation schemes but are also able to predict the of anatomical variations (Frijns et al. 2009b), species differences (Frijns et al. 2001), and

the effects of neural degeneration (Briaire and Frijns 2006; Snel-Bongers et al. 2013) (Fig. 3).

Auditory Thalamocortical Transformations

Kazuo Imaizumi and Charles C. Lee

Department of Comparative Biomedical Sciences,
School of Veterinary Medicine, Louisiana State
University, Baton Rouge, LA, USA

Definition

Auditory thalamocortical transformations arise from the ascending neural processing of spontaneous activity as well as external sound-evoked activity from the auditory thalamus, the medial geniculate body, to the thalamorecipient layers of the auditory cortex in mammals.

Detailed Description

Thalamic and Cortical Organization

The Thalamus

The thalamus is the obligate neural station conveying ascending sensory information to the cortex (Sherman and Guillery 2006; Jones 2007). Each sensory modality, except for olfaction, is represented in defined nuclei of the thalamus through which sensory information must first be processed before eventually being transmitted to the respective sensory areas of the neocortex (Sherman and Guillery 2006; Jones 2007). In the auditory system, the medial geniculate body is the main auditory thalamic nucleus (Winer 1984; Jones 2007). Classically, the medial geniculate body has been divided into three main subdivisions, i.e., the ventral division, the dorsal division,

and the medial division (Winer 1984; Imig and Morel 1985). Each of these thalamic nuclei can be identified on the basis of their cytoarchitecture, physiological properties, and connections (Huang and Winer 2000; de la Mothe et al. 2006; Lee and Winer 2008a). The thalamocortical transformation is constrained by the neuroanatomical organization of projections from each of these thalamic nuclei to each of the several areas of the auditory cortex (Winer et al. 2005; Winer and Lee 2007; Lee and Winer 2011b).

The Ventral Division of the Medial Geniculate Body
The ventral division of the medial geniculate body is the principal thalamic nucleus conveying ascending auditory information to the primary auditory cortex (Huang and Winer 2000; Smith et al. 2012). A subregion within the ventral division, the pars ovoidalis, is located in the medial part of the nucleus, bordering the dorsal division and medial division (Winer 1984; Jones 2007). Neurons in the ventral division are sharply tuned to sound frequencies (Imig and Morel 1985). These neurons are arranged in laminar rostrocaudal sheets, with their dendritic fields aligned in parallel along the sheet. The neurons in each sheet respond to similarly tuned frequencies (Imig and Morel 1985). These sheets are organized lateromedially in most species studied, with neurons in the lateral regions responding to lower frequencies of sound, while neurons in the medial regions respond to higher frequencies of sound (Imig and Morel 1985). Other physiological properties, such as bandwidth tuning and aurality, are found interdigitated among neurons across these isofrequency laminae (Ehret 1997). The main ascending projection to the ventral division originates from the central nucleus of the inferior colliculus (Calford 1983; Wenstrup 2005). These projections preserve the topographic organization connecting similarly tuned regions in the inferior colliculus to matched regions in the ventral division of the medial geniculate body (Wenstrup 2005). The main output of the ventral division is to the primary auditory cortex. These projections terminate primarily in layer 4 of the

primary auditory cortex but also have branched projections to layer 6 (Huang and Winer 2000; Smith et al. 2012). Similar to the projection from the inferior colliculus, these projections are also topographically organized, such that the low-frequency regions of the ventral division project to the lower-frequency regions of the primary auditory cortex (Morel and Imig 1987; Morel et al. 1993). The ventral division also connects with other tonotopically organized auditory cortical areas, which vary in number in different species, e.g., five in the cat (Reale and Imig 1980) and three in the monkey (Kaas and Hackett 2000). These areas also receive topographically organized projections from the ventral division but mainly from nonoverlapping sectors (Morel and Imig 1987). Very few neurons in the ventral division send branched projections to multiple auditory areas, i.e., low-frequency neurons in the ventral division do not connect with multiple low-frequency regions in different tonotopically organized areas (Lee et al. 2004, 2011).

The Dorsal Division of the Medial Geniculate Body
The dorsal division of the medial geniculate body is the part of the auditory thalamus that connects to non-tonotopically organized areas of the auditory cortex (de la Mothe et al. 2006; Lee and Winer 2008a). This nucleus is composed of various subnuclei, including the dorsal superficial, deep dorsal, dorsocaudal, and ventrolateral nuclei (Winer et al. 2005; Lee and Winer 2008a). Neurons in the dorsal division are broadly tuned to frequencies, many with multi-peaked and complex receptive fields (Morel and Imig 1987; Winer et al. 2005). In contrast to the organization of the ventral division of the medial geniculate body, neurons in the dorsal division do not exhibit an oriented laminar pattern of organization (Winer 1984). The dendritic arborizations of neurons in the dorsal division are more isotropically organized. The subdivision of this nucleus is based primarily on cytoarchitectonic densities and connections with several non-tonotopic auditory areas (Lee 2013). Projections to the dorsal division originate primarily from the non-tonotopic area of the inferior colliculus, i.e., the dorsal cortex (Wenstrup 2005). The dorsal division nuclei

project broadly to the non-tonotopic areas of the auditory cortex, which also include multimodal and limbic-related areas, whose relation to auditory processing in part is derived from the direct inputs received from thalamocortical sources (Lee and Winer 2008a, 2011a). Although a functional metric, such as tonotopy, appears to be absent in the nuclei of the dorsal division, their projections to the non-tonotopic areas of the auditory cortex are highly topographic, similar in extent to the topography of projections from the ventral division to the tonotopic regions of the auditory cortex (Lee and Winer 2005; Schreiner and Winer 2007). The termination pattern of the dorsal division projections to the non-tonotopic cortical areas, in particular, the secondary auditory cortical region, is similar to that of the ventral division projection to the primary auditory cortex, i.e., terminations primarily in layers 4 and 6 (Huang and Winer 2000). However, the synaptic terminals of the dorsal division projection to the secondary auditory cortex are slightly larger on average than the projections from the ventral division to the primary auditory cortex (Smith et al. 2012). Again, although the dorsal division projects broadly to several non-tonotopic auditory areas, very few neurons within the dorsal division send branched projections to multiple areas (Kishan et al. 2008; Lee and Winer 2008a; Lee et al. 2011).

The Medial Division of the Medial Geniculate Body
The medial division of the medial geniculate body projects widely across all auditory cortical areas, with a pattern of axonal termination that contrasts with the projections from the ventral division and the dorsal division of the medial geniculate body (Huang and Winer 2000; Jones 2007). Neurons in the medial division exhibit highly complex receptive fields, which often extend beyond purely auditory responses, with many neurons responding to stimuli from several modalities, i.e., visual and somatosensory (Bordi and LeDoux 1994). Neurons in the medial division differ from those in the ventral division and dorsal division, in that they display a wide range of sizes and dendritic arborization patterns (Bartlett and Smith 1999; Smith et al. 2007). The medial division contains the magnocellular neurons, which are

the largest neurons in the medial geniculate body (Winer 1984). Like the dorsal division, the neurons in the medial division do not appear to be organized isotropically along any particular anatomical domain and are loosely packed compared with the other divisions (Winer 1984). The medial division receives its primary input from both the dorsal cortex and external cortex regions of the inferior colliculus, which also contain non-tonotopic and multimodal responsive neurons (Wenstrup 2005). Every area of the auditory cortex receives a projection from the medial division (Lee and Winer 2008a), but unlike the ventral division and the dorsal division, the laminar terminations of axons in these areas are primarily concentrated in layer 1 (Huang and Winer 2000). While axonal divergence from the medial geniculate body is low in general, the highest proportion of neurons projecting to multiple auditory cortical areas is found in the medial division; however, these comprise on average less than 2% of neurons in the medial division of the medial geniculate body (Kishan et al. 2008, 2011; Lee et al. 2011).

Inhibitory Circuits in the Thalamus

The thalamic reticular nucleus, although not a specific constituent of the medial geniculate body, is intimately intertwined with the operations of both the thalamus and cortex and thus is an essential structural component of the thalamocortical transformation (Winer and Larue 1996; Crabtree et al. 1998; Pinault 2004; Sherman and Guillery 2006). The thalamic reticular nucleus is composed of inhibitory GABAergic neurons that form a shell surrounding the thalamus, roughly located along the lateral border of the thalamus and extending rostrocaudally along nearly its entire length (Pinault 2004; Lam and Sherman 2005, 2007, 2010). In general, each nucleus of the thalamus innervates a specific sector of the thalamic reticular nucleus and receives reciprocal topographic inhibitory feedback projections from that region of the thalamic reticular nucleus (Lam and Sherman 2005). In addition, feedback projections from layer 6 of the neocortex en route to the thalamus branch to innervate the thalamic reticular nucleus (Lam and Sherman

2010), which establishes an extended thalamocorticothalamic inhibitory feedback loop (Pinault 2004). The thalamic reticular nucleus and the inferior colliculus are the main sources of inhibition in the medial geniculate body of rodents, which contain very few local inhibitory neurons (Winer and Larue 1996). In humans, local inhibitory neurons in the medial geniculate body comprise ~20% of the total number of neurons, which is accompanied by a proportional reduction in inhibitory projections from the thalamic reticular nucleus, compared with rodents and other species, which have fewer than 1% of local inhibitory neurons in the medial geniculate body (Winer and Larue 1996).

The Cerebral Cortex

The cerebral cortex is phylogenetically the newest structure in the mammalian brain, responsible for the higher-order processing of sensory, motor, and limbic information (Kaas 2008). Broadly, the cerebral cortex is composed of regions of “gray” matter and “white” matter, the former residing near the outer cortical surface and containing all of the neuronal cell bodies and the latter residing beneath the gray matter and composed of the axonal fiber tracts of afferent and efferent projections (Nieuwenhuys 2013). Although regional variations exist, the gray matter of the cerebral cortex has a laminar organization divided into cytoarchitectonically distinguishable layers, such that neuronal cell bodies are situated in structural and functional groups relative to their location along the pial to white matter axis (Mountcastle 1997). These layers of neuronal cell bodies have specific afferent and efferent connections with other cortical regions and with subcortical structures, in particular the thalamus (Sherman and Guillery 2006). In total, there are six classically defined layers of the cortex (Mountcastle 1997). Of these, layer 4 of the cerebral cortex is the main recipient layer for sensory information ascending from the primary sensory thalamic nuclei (Sherman and Guillery 2006). In addition, layer 6 receives branched projection from these primary sensory thalamic nuclei (Huang and Winer 2000; Smith et al. 2012; Lee and Imaizumi 2013), and layer 1 is the recipient of thalamocortical inputs

from nonspecific thalamic nuclei, e.g., the medial division of the medial geniculate body (Huang and Winer 2000; Jones 2007). In addition, layer 6 is the source of neurons that send feedback projections to the thalamic nucleus that provides its main thalamocortical input in layers 4 and 6, which establishes a thalamocorticothalamic feedback loop (Sherman and Guillery 2006). Cortical layer 5 is the source of feedforward nonreciprocal thalamocortical projections, which serve as a conduit for communication between cortical areas via a corticothalamocortical route (Sherman and Guillery 2006).

The surface of the cerebral cortex is regionally specified into distinct functional areas that are involved in processing sensory and motor information (Kaas 2008). The boundaries of these cortical areas, including those involved with audition, are broadly defined based on their cytoarchitectural organization, connections with other structures, and physiological responses of constituent neurons, although precise borders and definitions for many cortical areas in different organisms still remain elusive (Kaas and Hackett 2000; Hackett 2011). Although all mammals have cortical regions devoted to the processing of auditory information, the number of auditory cortical areas varies widely among different species (Lee and Winer 2008b, 2011b). Despite this heterogeneity, all mammals studied thus far have an identifiable auditory cortical region that receives direct input from the ventral division of the medial geniculate body (Lee and Winer 2011b). This primary auditory cortical area is also defined on the basis of a clearly identifiable tonotopic map, which reflects the frequency segregation established in the cochlea and propagated along the auditory pathway (Ehret 1997).

Although the primary auditory cortical area is the most conserved across species, constellations of other cortical regions devoted to the processing of sound exist among the cortices of different mammalian species (Kaas 2008). However, their physiological and anatomical organization is generally less well understood relative to that of the primary auditory cortex. Nevertheless, these other areas can be broadly grouped into distinct categories: tonotopic, non-tonotopic, multimodal, and

limbic related (Lee and Winer 2011a). The tonotopic regions, like the primary auditory cortex, contain identifiable maps of frequency across their surface, generally with frequency reversals at their borders, and receive strong projections from the ventral division of the medial geniculate body (Reale and Imig 1980; Hackett et al. 1998; Hackett et al. 2011). The non-tonotopic areas contain disordered representation of frequency and generally receive more prominent inputs from the dorsal division of the medial geniculate body (Schreiner and Cynader 1984; Smith et al. 2012). Multimodal and limbic areas reside at the limits of the classical auditory areas and receive inputs from multimodal and limbic thalamic nuclei and areas and have complex responses reflective of these convergent inputs (Bowman and Olson 1988; Clarey and Irvine 1990; Clascá et al. 1997; de la Mothe et al. 2006). As discussed above, features of the thalamocortical inputs to these other areas resemble those to the primary auditory cortex (Huang and Winer 2000; Smith et al. 2012), which could serve as an anatomical basis for common thalamocortical transformations across the expanse of auditory cortical areas (Lee and Sherman 2008, 2011).

Receptive Fields and the Thalamocortical Transformation

Spectral Receptive Field

An important physiological parameter in the auditory thalamocortical transformation is the spectral receptive field. The spectral receptive field is, in general, measured based on a frequency-threshold tuning curve (response to sound level as a function of sound frequency). A common measure is the Q factor by which characteristic frequency is divided by a linear measure of bandwidth at a given sound level above threshold (e.g., Q_{10} ; Q value at 10 dB above threshold) (Imaizumi et al. 2004). Because the Q value is a normalized measure, the larger the Q value, the more sharply tuned are the neurons. Another measure is the square root transformation:

$$\sqrt{F_2} - \sqrt{F_1}$$

where $F2$ and $F1$ are the highest and lowest edges of bandwidth at a given sound level (Rouiller et al. 1981; Calford 1983). Unlike the Q value, the smaller the square root transformation value, the more sharply tuned are the neurons.

The auditory thalamocortical transformation is mediated by the excitatory neurotransmitter, glutamate, from the medial geniculate body to the auditory cortex. Therefore, only the excitatory receptive field is transformed in thalamocortical projections. A problem describing spectral receptive fields in the thalamocortical transformation is the availability of data utilizing the same recording method (e.g., local field potentials, single- or multiunit extracellular recording, whole-cell recording, etc.) under similar recording conditions (e.g., anesthesia: isoflurane, ketamine, or pentobarbital; depth of anesthesia; awake states; restricted or freely moving) in the same animal species. This creates some controversy and readers should use caution for the following section.

Functional organization of the spectral receptive field has been well appreciated in the auditory cortices of several species. The most well-known example is the primary auditory cortex of the mustached bat. A large area, called the DSCF (Doppler-shifted constant frequency) area, of the primary auditory cortex is devoted to a particular frequency range (60.6–62.3 kHz) for their prey-hunting behavior (Suga 1994). Neurons in the DSCF area are extremely sharply tuned to characteristic frequency ($Q50$ values range from ~10 to 500 or higher) (Suga and Manabe 1982; Suga et al. 1997). Neurons in the anterior and posterior parts of the DSCF area are more broadly tuned. Similarly organized clusters of sharply or broadly tuned neurons are also found in the auditory cortex of carnivores and primates (Recanzone et al. 1999; Cheung et al. 2001; Read et al. 2001; Imaizumi et al. 2004; Philibert et al. 2005; Imaizumi and Schreiner 2007). In particular, the cat primary auditory cortex has an interesting functional organization of spectral receptive fields. Sharply or broadly tuned neurons are clustered alternatively along the dorsoventral axis only in the mid-frequency range (5–20 kHz) (Imaizumi and Schreiner 2007). Unlike those animal species, functional organization of spectral

receptive fields in the rodent auditory cortex is not clear (Polley et al. 2007). Whereas rich information of functional organization of spectral receptive fields is available in the auditory cortex, only limited information is available in the medial geniculate body. Neurons in the ventral division are, in general, more sharply tuned than in the dorsal division (Rouiller et al. 1981; Calford 1983; Edeline et al. 1999). However, no clear spatial organization is available due to the deep location in the brain.

In general, it is believed that spectral receptive fields become broader through the thalamocortical transformation (Kaur et al. 2004, 2005). However, more recent studies using in vivo whole-cell recordings combined with pharmacological manipulation (blocking cortical input by muscimol and SCH50911) have revealed that thalamocortical input is not as sharp as was thought (Liu et al. 2007). These examples above are based on studies in rodents. Spectral receptive fields, however, vary widely across species. In the human auditory cortex, neurons are extremely sharply tuned (Bitterman et al. 2008), which suggests that spectral receptive fields may become sharper through the thalamocortical transformation. How does this opposite trend occur in thalamocortical transformation? Clear evidence is available in the awake mustached bat. Based on $Q10$, $Q30$, and $Q50$ values, DSCF neurons in the primary auditory cortex are more sharply tuned than those in the medial geniculate body (Suga et al. 1997). Similar evidence is also available in the awake marmoset (Bartlett et al. 2011). Thus, the sharpening of spectral receptive fields through the thalamocortical transformation may relate to behavioral and/or ethological functions.

For thalamocortical transformation of spectral receptive fields, limited experimental cases are available using in vivo single-unit recordings in awake guinea pigs (Creutzfeldt et al. 1980) and anesthetized cats (Miller et al. 2001, 2002). For secure functional transformation, medial geniculate body and auditory cortex neurons require an alignment of less than 1/3 octave difference in best frequency (sound frequency evoked the best response in a neuron at a given sound level)

(Miller et al. 2001). To fully activate a neuron in the auditory cortex, synaptic convergence from 20 to 25 neurons in the medial geniculate body is required (Miller et al. 2001). Using a ripple noise stimulus and computational analytical approach of reverse correlation technique, Miller et al. (2002) estimated spectral *modulation* rates through thalamocortical transformation. Both thalamic and cortical neurons show lower spectral *modulation* rates. Whereas cortical neurons have significantly lower spectral *modulation* rates than thalamic neurons based on the best spectral *modulation* rates, the overall spectral filter properties between thalamic and cortical neurons are similar.

Overall, spectral receptive (*modulation*) fields in the thalamocortical transformation are not simple. Depending on animals and the behavioral significance of sound frequency, spectral receptive fields become broader or sharper through the thalamocortical transformation.

Temporal Receptive Field

An important function of the central auditory system is to decode species-specific communications and human speech sounds. Periodic modulations are ubiquitous temporal features of species-specific communications and human speech sounds (Rosen 1992; Joris et al. 2004). Measuring repetition-rate transfer functions or modulation transfer functions captures response characterization to assess information for a temporal range that corresponds to periodicities in communication sounds (Eggermont 2001; Joris et al. 2004). Two commonly used measures to characterize repetition-rate transfer functions are firing rate and vector strength (VS). Firing rate estimates overall response magnitude in a particular time window. Vector strength estimates spike-timing precision to a particular phase of repetition or modulation stimulus:

$$VS = \frac{\sqrt{(\sum \cos \theta)^2 + (\sum \sin \theta)^2}}{n}$$

$$\theta = 2\pi \frac{t}{T}$$

where n is the total number of spikes, t is time of spike occurrence, and T is the interstimulus interval (Goldberg and Brown 1969). Significance of synchronization to the stimulus is examined by a Rayleigh test, >13.8 ($p < 0.001$) (Mardia 1972). Because vector strength does not incorporate response strength, it may give rise to high vector strength values when the response strength is low. To overcome a shortcoming of the VS measure, phase-projected vector strength (VS_{pp}) is used (Yin et al. 2011; Niwa et al. 2012). VS_{pp} compares the mean phase angle for each trial with the mean phase angle of all trials and penalizes single-trial vector strength values if they are not in phase with the global response. VS_{pp} is computed on a trial-by-trial basis as follows:

$$VS_{pp} = VS_t \cos(\phi_t - \phi_c)$$

where VS_{pp} is the phase-projected vector strength per trial, VS_t is the vector strength per trial, and ϕ_t and ϕ_c are the trial-by-trial and mean phase angle in radians, calculated for each stimulus condition, and,

$$\phi = \arctan 2 \frac{\sum_{i=1}^n \sin \theta_i}{\sum_{i=1}^n \cos \theta_i}$$

where n is the number of spikes per trial (for ϕ_t) or across all trials (for ϕ_c) and $\arctan 2$ is a modified version of the arctangent that determines the correct quadrant of the output based on the signs of the sine and cosine inputs. Whereas vector strength value ranges from 1 (all spikes occur at the same stimulus phase) to 0 (spikes occur randomly), phase-projected vector strength value ranges from 1 (all spikes in phase with population mean phase) to -1 (all spikes 180° out of phase with population mean phase) with 0 corresponding to randomly occurring spikes (Yin et al. 2011; Niwa et al. 2012). Another way to overcome a shortcoming of vector strength is the product of two measures (vector strength and firing rate), i.e., phase-locked rate or synchronized rate (Eggermont 1998b; Joris et al. 2004; Imaizumi et al. 2011). The synchronized rate measure incorporates both timing and response strength measures.

Two coding schemes for temporal receptive fields have been proposed: precise spike timing estimated by vector strength codes slow repetition rates (or modulation frequencies), while firing rate codes faster repetition rates (De Ribaupierre et al. 1972; Bieser and Muller-Preuss 1996; Schulze and Langner 1997; Lu and Wang 2000; Lu et al. 2001; Joris et al. 2004). However, more recent studies have proposed different coding schemes, as will be described later.

A problem describing temporal receptive fields in the thalamocortical transformation is also the availability of data utilizing the same stimulus (e.g., nature of stimulus: click or white noise; modulation carrier: pure tone or noise; modulation depth; and modulation shape: rectangular or sinusoidal), stimulus presentation method (free field or sealed earphones), and recording method (single- or multiunit extracellular recording) under similar recording conditions (e.g., anesthesia: isoflurane, ketamine, or pentobarbital; depth of anesthesia; awake states: restricted, freely moving, or engaged behavior) in the same animal species. In many cases, the analytical criteria are also different. These create difficulty for direct comparisons and some discrepancy. Thus, the readers should treat the following section with caution.

The vast majority of studies regarding temporal receptive fields have focused on the primary auditory cortex. However, functional magnetic resonance imaging or positron emission tomography in humans and macaques suggested that the superior temporal plane is specific to human speech or macaque species-specific calls over nonspecific calls or other sounds (Belin et al. 2000; Poremba et al. 2004; Petkov et al. 2008). These fields are located anterior to the primary core fields and may correspond to the rostral field in primates. Reversible lesion experiments in cats also show that the anterior auditory field is specific to temporal pattern discrimination (Lomber and Malhotra 2008). Thus, the rostral field in primates and the anterior auditory field in carnivores (and rodents) may be more important for temporal pattern processing.

Rodent Auditory Cortex and Thalamus

Under anesthesia of pentobarbital, neurons in the rat primary auditory cortex, in general, show a low-pass filter property of repetition-rate transfer functions by rate coding (firing rate) or band-pass filter property by temporal coding (vector strength) (Kilgard and Merzenich 1999; Chang et al. 2005). Ter-Mikaelian et al. (2007) examined the effects of anesthesia (a combination of pentobarbital and ketamine) and awake (head-fixed) states in the gerbil primary auditory cortex. While anesthesia certainly affects modulation transfer functions in individual neurons, overall, the population response seems to be similar between anesthesia and awake states (Ter-Mikaelian et al. 2007). Clear evidence of an effect of anesthesia is available in the rat primary auditory cortex (Rennaker et al. 2007). Ketamine anesthesia significantly decreased cutoff repetition rates (higher border of repetition-rate transfer function) to <20 Hz from 80 to 90 Hz in the awake state. A more recent study using awake state (head-fixed) rats examined repetition-rate transfer function using click trains in the primary auditory cortex and the anterior auditory field (Ma et al. 2013). Both core fields show high best repetition rates (up to 32–64 Hz) and cutoff repetition rates (up to 256 Hz), although neurons in the anterior auditory field prefer significantly higher repetition rates than those in the primary auditory cortex. These best and cutoff repetition rates in the awake rat auditory cortex are, in general, higher than those in the anesthetized rat (Kilgard and Merzenich 1999; Chang et al. 2005). Attention or engaged behaviors also alter temporal receptive fields. By presenting at 15 Hz repetition rate (with various carrier frequencies) paired with electrical stimulation of the nucleus basalis for 20–25 days, neurons in the rat primary auditory cortex are capable of following higher repetition rates by rate coding than those in control (Kilgard and Merzenich 1998). Training in a sound maze in which rats use sound source location for food rewards based on auditory cues (noise repetition rates increased with decreasing distance between the rat and target location) also enhanced temporal receptive fields (Bao et al. 2004). Compared to

studies in the rodent auditory cortex, a small number of studies are available in rodent thalamus. In awake guinea pigs, thalamic neurons show more robust responses to higher modulation frequencies than cortical neurons (Creutzfeldt et al. 1980).

Cat Auditory Cortex and Thalamus

The cat auditory cortex has been a focus of studies of temporal pattern processing. In particular, the primary auditory cortex and the anterior auditory field are readily identifiable based on their location relative to sulcal patterns (Knight 1977; Imaizumi et al. 2004; Lee et al. 2004) and are often compared in temporal pattern processing (Schreiner and Urbas 1988; Eggermont 2000; Joris et al. 2004). Under anesthesia, neurons in the anterior auditory field prefer higher modulation frequencies (and repetition rates) than those in the primary auditory cortex (Schreiner and Urbas 1988; Eggermont 1998b). Anesthesia also reduces temporal receptive fields by half in neurons of the cat primary auditory cortex (Goldstein et al. 1959). In the cat anterior auditory field under ketamine anesthesia, Imaizumi et al. (2010) proposed different coding schemes using a combination of an *in vivo* high-resolution cortical mapping technique with information theory. Because this study was made using multiunit recordings, they computed discriminability of six different low repetition rates (1–30 Hz) (Imaizumi et al. 2010). Unlike the traditional coding scheme (precise spike timing codes low repetition rates), inter-spike intervals can carry much more information than timing and rate codes: some multiunits carried an information value >2 bits that is close to a maximum of ~ 2.58 bits ($=\log_2(6)$). Furthermore, spatial distribution of normalized firing rate to six different repetition rates differs across the stimuli, which provides a potential coding scheme in the view of an ideal observer. These results suggest concurrent coding schemes of temporal pattern processing by inter-spike intervals, firing rate, and a map (Imaizumi et al. 2010). Using behaviorally trained cats, Dong et al. (2011) compared neurometric (neural responses to six repetition rates from 12.5 to 200 Hz by *in vivo* single-unit recordings) with psychometric (Go/No-Go behavioral responses to the same six

repetition rates) functions. Their recordings were focused on the relatively low-frequency locations <16 kHz of the primary auditory cortex. Prevalence is found of more synchronized units in the behaviorally engaged primary auditory cortex than in an anesthetized one (Lu and Wang 2000; Dong et al. 2011). However, rate coding by non-synchronized units correlates well with psychometric functions.

Compared to the studies in the cat auditory cortex, a small number of studies are available in the cat thalamus. In nitrous oxide-anesthetized cats, approximately half of the thalamic units showed precisely time-locked responses to click trains (Rouiller et al. 1981). Half of these units had cutoff repetition rates (higher border of repetition-rate transfer function) up to 100 Hz. Local field potentials in the auditory cortex record subthreshold responses potentially from thalamocortical fibers (and corticocortical fibers), thus indicating thalamic responses. Both best modulation frequencies and cutoff modulation frequencies are generally higher in local field potentials than unit recordings in the primary auditory cortex and anterior auditory field (Eggermont 1998b). Under ketamine anesthesia in the primary auditory cortex and the ventral division of the medial geniculate body of cats, Miller et al. (2002) conducted *in vivo* simultaneous single-unit recordings from thalamus and cortical neurons. They found that temporal modulation transfer functions are significantly deteriorated through thalamocortical projections.

Primate Auditory Cortex and Thalamus

A majority of studies of temporal receptive fields in primates are conducted in the awake state. In the awake squirrel monkey, neurons in the primary auditory cortex and the rostral field show both temporal and rate codes to amplitude modulation frequencies up to 64 or 128 Hz (Bieser and Muller-Preuss 1996). Neurons in the primary auditory cortex showed higher best modulation frequencies than those in the rostral field. In the awake macaque, neurons in the primary auditory cortex have higher best modulation frequencies by both temporal (means are 13 and 4.8 Hz) and rate (means are 45 and 19 Hz) codes and higher

vector strength than those in the rostral field (Malone et al. 2010; Scott et al. 2011). These examples from the awake squirrel monkey and macaque have suggested the opposite trend of temporal receptive fields in the core auditory fields to rodents and cats (Schreiner and Urbas 1988; Eggermont 1998b; Joris et al. 2004) despite the similar cortical locations (relative to the primary auditory cortex) of the anterior auditory field in rodents and cats and the rostral field in the primates. In the awake primate auditory cortex, neurons may carry both temporal and rate codes for lower and higher repetition rates (or modulation frequencies) (Bieser and Muller-Preuss 1996; Lu et al. 2001; Liang et al. 2002; Malone et al. 2007; Yin et al. 2011). However, a proportion of synchronized (using vector strength or similar measures) and non-synchronized (using firing rate) neurons are different among the studies. These discrepancies may be caused by the stimulus, the range of repetition rates, and/or analytical criterion (Yin et al. 2011). There is an interesting proposal of low to mid range of repetition rates (10–45 Hz) corresponding to flutter perception by two different populations of neurons in the awake marmoset auditory cortex. One population of neurons increases firing rate with increasing repetition rates, while the other population decreases firing rate with increasing repetition rates (Bendor and Wang 2007). All examples reviewed above are based on studies of primates passively listening to stimuli in awake state. However, active engagement of behaviors (discriminating modulated sounds, 2.5–500 Hz, from unmodulated sounds) improves both temporal and rate codes in single neurons of the macaque primary auditory cortex (Niwa et al. 2012).

Compared to the studies in primate auditory cortex, a small number of studies are available in primate thalamus. In the awake squirrel monkey, neurons in the thalamus show a similar tendency of temporal and rate coding to best modulation frequencies up to 128 Hz (Preuss and Muller-Preuss 1990). In the awake marmoset, neurons in the ventral and the anterodorsal divisions of the medial geniculate body show a mixture of temporal and rate coding, while neurons in the

posterodorsal division show a dominant tendency of rate coding (Bartlett and Wang 2011). These examples suggest that separation of temporal and rate coding for low and high repetition rates may be created within the auditory cortex (Bartlett and Wang 2007). However, other data suggest that separation from temporal to rate coding for low to high repetition rates may be completed through thalamocortical transformation (Malone et al. 2007; Yin et al. 2011). Thalamic neurons are capable of following higher repetition rates by both temporal and rate coding than cortical neurons in the awake marmoset (Bartlett and Wang 2007).

Overall, temporal receptive fields change through the thalamocortical transformation. In general, thalamic neurons are more capable of following higher repetition rates (modulation frequencies) than cortical neurons. However, neurons in the auditory cortex may employ different coding schemes to follow different ranges of repetition rates (this is not restricted only to high repetition rates but also low to mid repetition rates) either through the thalamocortical transformation or at the cortical level.

Latency

First-spike latency (hereafter latency) is another important physiological parameter (Eggermont 2001). However, because only the experimenter knows the stimulus onset (the brain and neurons do not know it), relative latencies might be a good candidate for neural coding of temporal patterns (Eggermont 1998b; Schreiner and Raggio 1996; Lu and Wang 2000; Liang et al. 2002; Ter-Mikaelian et al. 2007; Imaizumi et al. 2011), vocalizations (Wang et al. 1995; Nagarajan et al. 2002), sound localization (Eggermont 1998a; Furukawa et al. 2000), and auditory scene (Dear et al. 1993). Latency, in general, decreases with increasing sound level (Heil 1997). However, neurons in the primary auditory cortex of the little brown bat show shorter latencies to lower sound level than higher sound level (Sullivan 1982b). Furthermore, when the two sounds (higher and lower sound levels) are presented by a behaviorally relevant delay between pulse and echo, latencies are facilitated and become shorter for the

echolocating behavior (Sullivan 1982a). In general, neurons in the anterior auditory field have shorter latencies than those in the primary auditory cortex across many different species (Schreiner and Urbas 1986, 1988; Linden et al. 2003; Rutkowski et al. 2003; Imaizumi et al. 2004; Bizley et al. 2005). However, neurons in the primate primary auditory cortex show shorter latencies than those in the rostral field (Scott et al. 2011), which is related to the fact that neurons in the primate primary auditory cortex follow higher repetition rates than those in the rostral field (Bieser and Muller-Preuss 1996; Malone et al. 2010).

Neurons in the ventral division of the medial geniculate body show shorter latencies than those in other divisions (Rouiller et al. 1981; Calford 1983; Edeline et al. 1999). However, more recent studies in the mouse and guinea pig thalamus show that neurons in the medial division have shorter latencies than those in the ventral division of the medial geniculate body (Anderson et al. 2006; Anderson and Linden 2011). This evidence strongly supports the shorter latencies in neurons of the anterior auditory field than those in the primary auditory cortex (Schreiner and Urbas 1986, 1988; Linden et al. 2003; Rutkowski et al. 2003; Imaizumi et al. 2004; Bizley et al. 2005) because the anterior auditory field receives input not only from the ventral division but also from the medial division. Latency through thalamocortical transformation can be estimated by in vivo simultaneous single-unit recordings and cross-correlation analysis. A maximum peak in the correlogram is shifted to the expected travel and synaptic delay (e.g., a few milliseconds) (Miller et al. 2001). Thus, it is generally believed that latency in thalamocortical transformation is inherited from the thalamus to cortex. However, a recent study using in vivo whole-cell recordings combined with a pharmacological application (to silence cortical activity by a mixture of muscimol and SCH50911) in the rat primary auditory cortex unfolds a different story: difference in latency between the thalamus and cortex is generated by synaptic integration time by excitation and inhibition through corticocortical interactions (Zhou et al. 2012).

Auditory-Nerve Response, Afferent Signals

Peter Heil

Systems Physiology of Learning, Leibniz Institute for Neurobiology, Magdeburg, Germany

Definition

Sequences of action potentials (spikes) of individual auditory-nerve fibers (ANFs), the primary auditory afferents, in response to sounds impinging upon the ears.

Detailed Description

Anatomical Foundations

Acoustic information relayed from the inner ear to the central nervous system is encoded in the sequences of spikes produced by (type I) ANFs. In mammals, each ANF contacts only one receptor cell (an inner hair cell, IHC) and is excited by transmitter release events from a single ribbon synapse (Ashmore 2010; Matthews and Fuchs 2010; Chapochnikov et al. 2014). Each IHC has 5–30 ribbons, depending upon species and cochlear location (e.g., Meyer et al. 2009; Zhang

et al. 2018). The ANFs innervating a given IHC therefore share some, although not all, functional response properties.

Spontaneous Activity

ANFs produce spikes in the absence of external sound (spontaneous activity). The mean spontaneous rate varies between ANFs, in mammals from near zero up to more than 100 spikes per second (e.g., Liberman 1978; Temchin et al. 2008), even between ANFs innervating the same IHC (Wu et al. 2016). The timing of the spikes of a given ANF during spontaneous activity is highly variable. The spike-count statistics and the distribution and serial correlation of inter-spike intervals in an ANF spontaneous spike train can be understood as the result of excitatory transmitter release events produced by the random depletion and random replenishment of a small number of identical but independent presynaptic release sites at each ribbon, in combination with the ANF's refractory properties (Peterson and Heil 2018).

Driven Activity

Sounds impinging on the ipsilateral ear, when of appropriate spectral composition and amplitude, affect the spiking behavior of ANFs, most often increasing the spike rate. A threshold sound level may be defined at which the driven rate of a given ANF exceeds its spontaneous rate by some criterion. The compound action potential (CAP), a gross stimulus-evoked potential which reflects a weighted sum of ANF responses (Bourien et al. 2014), can be recorded in or near the cochlea, such as at the round window.

Frequency Tuning

Each ANF is tuned to sound frequency and is most sensitive, i.e., threshold is lowest, at a particular frequency (the characteristic frequency, CF) which is determined by the position along the cochlear partition of the IHC which it contacts (cochleotopy). Threshold versus frequency curves (tuning curves) are approximately V-shaped but have a plateau region above CF with very high thresholds (Huang and Olson 2011), and curves for high-CF ANFs exhibit low-frequency tails. The sharpness of tuning is often quantified by

the Q-value, defined as the CF divided by the bandwidth of the tuning curve at some level (e.g., 10 dB) above threshold at CF. Q_{10} -values increase with increasing CF (in cats from about 1 to 10 for CFs from 0.2 to 10 kHz; Pickles 2012) but can reach exceptionally high values (>200) in behaviorally relevant frequency ranges in species such as echo-locating bats.

Sound Level Dependence

With increasing sound level, the mean spike rate of a given ANF increases before saturating at several hundred spikes per second at higher sound levels. The range of sound levels over which the spike rate increases (the dynamic range, DR) varies between ANFs. DR is inversely related to the spontaneous rate of an ANF which in turn covaries with the ANF's sensitivity (e.g., Winter et al. 1990). For a given ANF, DR varies with sound frequency and is largest at CF due to compressive growth of mechanical responses in the inner ear with sound level. For frequencies below CF, where the mechanical responses are linear, the increase of the spike rate can be described by a Hill equation with a Hill coefficient of 3 and with the independent parameter being the sum of the sound amplitude and a baseline (Heil et al. 2011). DR and maximum spike rate also adapt to stimulus statistics (Wen et al. 2009).

Adaptation

Adaptation is also manifest as a decrease in spike rate over time in response to sounds of constant amplitude. Within a few milliseconds, the spike rate drops rapidly and then more gradually. The decrease can be modeled as the sum of multiple exponential decays with different time constants and a fractional power law (Zilany et al. 2009; Bruce et al. 2018). Upon cessation of the sound, the spike rate temporarily decreases below the spontaneous rate before recovering over tens to hundreds of milliseconds.

Phase Locking

In response to low-frequency sounds or broadband sounds containing low frequencies, ANFs exhibit phase locking, i.e., spikes are

nonrandomly distributed across the period of a low-frequency component (van der Heijden and Joris 2006; Heil and Peterson 2017). Phase locking is often quantified by the measures of vector strength and of the phase angle of the mean vector. For a given ANF, vector strength (a measure of the degree of phase locking) and phase angle of the mean vector vary with frequency and sound level. Across ANFs, maximum vector strength decreases with increasing frequency in a low-pass fashion, with cutoffs of a few kilohertz, depending on species. Phase locking is also seen in the responses of low-CF ANFs to acoustic clicks, elicited by multiple mechanical responses caused by these brief broadband sounds (Guinan 2012). ANFs also phase lock to the modulation envelope of sinusoidal amplitude-modulated tones and noise (e.g., Michelet et al. 2012).

For more detailed reviews of auditory-nerve responses, see Pickles (2012) and Heil and Peterson (2015, 2017). Several of these properties can be altered by sensorineural hearing loss (for reviews, see Young 2012, Henry and Heinz 2013). Loss of ANFs or of their synapses with IHCs can lead to overt and hidden hearing losses (e.g., Kujawa and Liberman 2009). Cochlear implants function by evoking spiking activity in ANFs.

Automated Parameter Search in Small Network Central Pattern Generators

Tomasz G. Smolinski
Department of Computer and Information Sciences, Delaware State University, Dover, DE, USA

Definition

Automated parameter search in small network central pattern generators (CPGs) involves the use of any methods other than manual (i.e., hand-tuning) to generate or tune sets of

parameters that result in physiologically realistic neuronal models of the CPGs. Such methods include “brute-force” explorations of predefined parameter spaces, as well as various heuristics (e.g., multi-objective evolutionary algorithms) used to arrive at a single or more of viable model parameter combinations.

Detailed Description

Central pattern generators (CPGs) are neural networks that produce rhythmically patterned outputs, without relying on any sensory feedback (Hooper 2001). CPGs drive such critical rhythmic activity as breathing, chewing, swimming, walking, heartbeat control, etc. CPGs have been shown to produce rhythmic outputs akin to normal rhythmic activity patterns, even in isolation from other parts of the nervous system, which makes them popular physiological models. Furthermore, due to their relative simplicity, especially in such model organisms as lobsters, crabs, or leeches, CPGs have also become quite widespread in computational modeling studies of cellular and synaptic properties of individual neurons and small neural networks.

While hand-tuning has been traditionally used in the process of creating CPG neuronal models (e.g., Soto-Treviño et al. 2005), in light of recent advances in the computational capabilities of modern computing systems, which now facilitate the use of more complex neuronal models (i.e., in terms of the number of compartments or free parameters), and allow for the exploration of unprecedentedly large parameter search spaces, this approach has become virtually obsolete. Therefore, automated methods for model parameter search have been lately gaining much attention.

There are basically two approaches to the problem of searching for optimal (i.e., physiologically realistic) sets of parameter values for models of small network central pattern generators: (1) “brute-force” explorations of predefined parameter spaces and (2) explorations utilizing heuristic optimization approaches, such as multi-objective evolutionary algorithms (MOEAs).

“Brute-Force” Explorations of Predefined Parameter Spaces

In the case of “brute-force” explorations of predefined parameter spaces, the study usually starts with a hand-tuned model of the CPG, which serves as the “center” for the parameter search space that is created around it. Then, physiologically realistic ranges for the model parameters (e.g., maximal conductances of membrane and synaptic currents) are chosen, along with the granularity for each of the parameters. The granularity determines how many possible values each of the parameters can assume and does not have to be the same for all the parameters, as some of them will exhibit different sensitivities to changes in their values. In some cases, the first step may be omitted and only the parameters, along with their ranges and granularities, are determined.

After such a grid-based parameter search space has been constructed, all of the possible combinations of the parameter values are simulated and tested for their physiological adequacy (possibly under multiple simulation scenarios, such as spontaneous activity, response to current injections, removal of neuromodulation, etc.). Only those models that match the behavior of the biological CPG, which is determined by means of one or more quantitative or qualitative measures of the CPG’s characteristics (e.g., spike height, interspike interval, burst duration, period, preservation of the phase of the rhythm, etc.), are retained for further analyses. However, the rejected models are also sometimes subjected to examination in order to determine what makes “bad” models unacceptable.

Explorations Utilizing Heuristic Optimization Approaches

In the case of explorations utilizing various heuristic approaches, such as multi-objective evolutionary algorithms, the study usually starts with the determination of the model parameters, along with their ranges and granularities, similarly to the “brute-force” approach, but often on a much larger scale. In other words, while the range in

the “brute-force” approach may reflect a 3- to four-fold variation in the parameter values, and the granularity may allow for five to ten possible values, incorporating up to 20-fold variation with hundreds of possible values for each parameter is not unheard of in a heuristic approach. Since this approach is not tasked with simulation and analysis of all of the possible combinations of values in such created parameter search space, it remains computationally feasible.

Another critical step in this approach is the definition of one or more measures of the given CPG’s characteristics that will be used to determine physiological adequacy of the models. While such measures can be virtually identical to the ones used in the “brute-force” approach, the difference lies in the fact that they are being used during the process of model generation itself, rather than at the end to filter out the unwanted models. These measures, in essence, become the fitness functions utilized in the process of optimizing model parameter values to drive it toward generating as many as possible “good” models which match the biological system, while limiting the number of “bad” solutions.

After the model parameters and the corresponding ranges and granularities have been determined, and the appropriate fitness functions (possibly multiple, even conflicting) have been defined, the iterative process of optimization of the model parameter values begins and ultimately yields a collection of physiologically realistic CPG models.

Applications

Most of the hitherto applications of the automated parameter searches in small network central pattern generators have been performed in relatively simple invertebrate CPGs. For example, Doloc-Mihu and Calabrese (2011) utilized the “brute-force” approach to construct a large (on the order of terabytes) database of conductance-based models of the half-center oscillator from the leech heartbeat central pattern generator to determine how neuronal parameters influence the network activity. Using the same approach, Günay and Prinz (2010) utilized a

large (20,250,000) database of models of the lobster pyloric network to study calcium sensors for network homeostasis. Smolinski, Prinz et al., used both the “brute-force” approach and multi-objective evolutionary algorithms to study the cellular and synaptic properties of the AB/PD (anterior burster/pyloric dilator) pacemaker kernel in the lobster pyloric network (2006, 2009), as well as the conductance correlations involved in the recovery of bursting after neuromodulator deprivation (Shim et al. 2012; Malik et al. 2013).

Axon Model

► Peripheral Nerve Models

Axon, Modeling

Bruce Graham
University of Stirling, Stirling, UK

Definition

Computational modeling of axons is used to determine the action potential initiation and propagation properties along these long and highly branched structures. Issues under investigation include the site and threshold of action potential initiation, propagation speed in unmyelinated and myelinated axons, and safety factors of propagation through branch points and other geometrical inhomogeneities, such as presynaptic boutons. Modeling allows exploration of the interaction between axonal morphology (diameters and branching structure) and passive and active membrane properties in determining the speed and reliability of action potential propagation. This can include the effects of ion channel noise. Modeling is also used to explore axonal development, including growth cone guidance and branching.

Detailed Description

The axon is the principle communication pathway from one neuron to another. Brief voltage pulses called action potentials (AP) are initiated near the cell body and travel along the axon to reach the many presynaptic boutons. The AP causes neurotransmitter release in a bouton in a stochastic manner, resulting in an electrical response in a target neuron. The reality is more complex than this: AP propagation is not always reliable due to geometrical and electrical constraints in the axon; timing of AP arrival at boutons may vary, having

implications for information processing in target nuclei; and AP shape in boutons will influence transmitter release. The experimental data showing these effects is nicely summarized in Debanne (2004). How theoretical results and computational models have been used to aid our understanding of these processes is described in Segev and Schneidman (1999), a paper that is still highly relevant to the field.

Computational modeling is also making a significant contribution to our understanding of how axons develop, from their differentiation from dendrites at initiation to their guidance to target structures and formation of functional connections. This work is documented by van Ooyen in a recent review (van Ooyen 2011) and in an edited volume (van Ooyen 2003).

Hodgkin-Huxley Model of the Action Potential

Computational modeling of the action potential in axons begins with the work of Hodgkin and Huxley in determining a model based on experimental data of the action potential in the squid giant axon (Hodgkin and Huxley 1952). Their model forms the basis of most subsequent models of action potentials and also of models of current flow through membrane-bound ion channels in general in the nervous system. Based on their experimental data, they formulated models of the electrical currents generated by the flow of sodium (Na) and potassium (K) ions across the membrane. Importantly, these currents are voltage sensitive, so that a membrane depolarization results in an increase in the sodium current, which in turn leads to further depolarization and an increase in the sodium current through a positive feedback mechanism. This activation of the sodium conductance is curtailed by a rapid inactivation. The potassium current also increases with depolarization, but more slowly than the sodium current. Eventually, the potassium current grows large enough that it, along with the inactivation of the sodium current, leads to a repolarization of the membrane. This entire process takes place within a few milliseconds, forming a sharp voltage wave of around

Axon, Modeling, Fig. 1 Action potential (AP) in a long, uniform axon. (a) AP over time at 25% along the axon. (b) AP over space after 20 ms. Simulation performed using the NEURON simulator

100 mV, which is the action potential (Fig. 1a). The basic model describes changes in the transmembrane voltage (V_m) in an isopotential patch of neuronal membrane as a function of membrane capacitance (C_m), sodium (I_{Na}) and potassium (I_K) ionic currents, a nonspecific “leak” current (I_L), and experimentally injected electrode current (I_e ; to initiate the action potential). The equations of this model are as follows:

Membrane Voltage

$$C_m \frac{dV_m}{dt} = -g_L(V_m - E_L) - g_{Na}m^3h(V_m - E_{Na}) - g_Kn^4(V_m - E_K) + I_e$$

Sodium Current

$$I_{Na} = g_{Na}m^3h(V - E_{Na}) \frac{dm}{dt} = \alpha_m(1 - m) - \beta_m m$$

$$\frac{dh}{dt} = \alpha_h(1 - h) - \beta_h h$$

$$\alpha_m = 0.1 \frac{V + 40}{1 - \exp(-(V + 40)/10)} \beta_m = 4 \exp(-(V + 65)/18)$$

$$\alpha_h = 0.07 \exp(-(V + 65)/20) \beta_h = \frac{1}{\exp(-(V + 35)/10) + 1}$$

Potassium Current

$$I_K = g_Kn^4(V - E_K) \frac{dn}{dt} = \alpha_n(1 - n) - \beta_n n$$

$$\alpha_n = 0.01 \frac{V + 55}{1 - \exp(-(V + 55)/10)} \beta_n = 0.125 \exp(-(V + 65)/80)$$

Action Potential Propagation

This model can be extended to include action potential propagation along the axon using these membrane active properties (sodium and potassium currents) in a compartmental model of an elongated axon (Fig. 1b). The compartmental model arises as a spatial discretization of the partial differential equation describing spatially extensive current flow along an axon:

$$C_m \frac{\partial V_m}{\partial t} = \frac{d}{4R_a} \frac{\partial^2 V}{\partial x^2} - g_L(V_m - E_L) - g_{Na}m^3h(V_m - E_{Na}) - g_Kn^4(V_m - E_K)$$

For the simulation shown in Fig. 1, the axon is a cylinder 300 mm long, with a uniform diameter of 476 μm . It is divided into 500 equal-length computational compartments to obtain the numerical solution. The simulation was performed using the NEURON simulator (Carnevale and Hines 2006) with code derived from that used in Chap. 3 of *Principles of Computational Modeling in Neuroscience* (Sterratt et al. 2011).

Speed and Reliability of Propagation

Axons are rarely simply long, uniform cylinders. Many axons become highly branched as they near their target structures. Diameters can change along

the length of the axon, with a general tapering to thinner diameters toward terminals but with large increases in diameter at presynaptic boutons. Branch points may impose a change in electrical load, depending on the diameters of the daughter branches. The work of Rall and colleagues (see collected papers in Segev et al. 1995) established the important concept of the geometrical ratio (GR) between the diameters of two daughter branches (d_1 and d_2) to that of the parent branch (d_p ; section of axon or dendrite closer to the cell body), defined as.

$$GR = \frac{d_1^{3/2} + d_2^{3/2}}{d_p^{3/2}}$$

Given uniform membrane properties, if $GR = 1$, the branch point imposes no change in electrical impedance, and the branching can be collapsed to an equivalent uniform cylinder. However, if $GR > 1$, the branch point imposes an extra electrical load that slows the AP, reduces its height, and can potentially lead to a failure of AP propagation. In contrast, if $GR < 1$, AP velocity and its height both increase as the branch point is approached, and propagation is reliable. Goldstein and Rall (1974) provided the first comprehensive computational investigation of AP propagation through specified geometrical inhomogeneities. An example is shown in Fig. 2. Here there is a single bifurcation in a long axon. The parent axon (at the left) has a diameter of

1 μm . The two daughter branches have an equal diameter of 2.52 μm , giving $GR = 8$. The action potential (AP) traces are from the parent axon, branch point, and one daughter branch, as illustrated in the figure. In this configuration (solid lines in time plots), the AP is significantly slowed and reduced in amplitude at the branch point (second trace from left), before quickly recovering and increasing in velocity. If the daughter diameters are reduced to 0.63 μm , then $GR = 1$, and the configuration is equivalent to a single, uniform axon of 1 μm diameter. In this case, the AP propagates with uniform amplitude and velocity (dashed lines). Note that though the AP at the branch point is significantly delayed when $GR = 8$, compared to $GR = 1$, the larger daughter branch diameter results in a higher velocity for the AP once it is through the branch point, and it quickly overtakes the AP traveling in the uniform axon (right-hand solid and dash plots, respectively). Goldstein and Rall (1974) showed that for axons with the same membrane (R_m) and axial (R_a) resistivity, AP speed is constant in units of length constant per unit time, irrespective of diameter (d). The passive length constant (λ) is.

$$\lambda = \sqrt{\frac{dR_m}{4R_a}}$$

This equates to an increase in speed in units of physical length per unit time with an increase in diameter.

Axon, Modeling, Fig. 2 Action potential (AP) in a branched axon. Recording sites illustrated at *left*. Traces of APs over time shown at *right*. *Solid lines*: $GR = 8$. *Dashed lines*: $GR = 1$. Simulations performed using the NEURON simulator

Manor et al. (1991) considered AP propagation in realistic axonal branching structures, with a particular emphasis on the delays imposed by geometrical irregularities. This study shows that though delays in AP propagation at individual branch points are at most small (a few tenths of a millisecond), accumulated delays in a complex, branching axon can result in arrival times at boutons differing by a few milliseconds. Delays or speedups from successive, nearby branch points do not sum linearly. In particular, successive summed delays may be supralinear compared to the delays at the individual, isolated branch points.

Differential branch point failure, in which the AP fails to propagate along one daughter branch, while successfully propagating along the other, which has been seen experimentally (Debanne 2004), cannot arise due to the branch point geometry alone (Segev and Schneidman 1999). Changes in the active membrane properties are also required and may arise due to differences in ion channel distributions between branches or differential extracellular ion accumulation during successive AP propagations leading to alterations in ion current reversal potentials (particularly E_K ; see the Hodgkin-Huxley model current equations) and hence current magnitudes.

In summary, computational modeling has been fundamental to improving our understanding of the characteristics of and constraints to AP propagation along branched and irregular axons.

Myelinated Axon

Propagation speeds along axons containing a continuous distribution of ion channels along their length (so-called unmyelinated axons) are rather modest, on the order of <1 m/s. Most long axons in the nervous system are myelinated, with glial cells providing a high-resistance membrane sheath around the axons for much of their length. Ion channels are largely restricted to the sites of regular breaks in this sheath, known as *nodes of Ranvier*. Action potential propagation speeds are much greater along these axons than along unmyelinated fibers, on the order of 10–100 m/s.

Computational modeling contributes to our understanding of AP propagation along

Axon, Modeling, Fig. 3 Myelinated axon. Structural details around a node of Ranvier

myelinated axons, particularly the implications of the very specific locality of sodium and potassium ion channels at and around the nodes of Ranvier (Fig. 3). Sodium channels are located at the node, with potassium channels largely restricted to the paranodal region.

In a simplistic approach, myelination may be modeled as an increased passive resistance and a decreased capacitance of the internodal (myelinated) axonal membrane, along with non-uniform distribution of active sodium and potassium channels. However, the narrow extracellular (periaxonal) space afforded by the myelination, plus the spatial separation of sodium and potassium channels, may require the modeling of ion concentrations and the electro-diffusion of ions intra- and extracellularly, to fully capture the action potential propagation properties of the myelinated axon (Nygren and Halter 1999).

Models show that excessive accumulation of potassium in the periaxonal space following high-frequency repetitive activity can lead to action potential failure (Parnas and Segev 1979). Models are also used to explore the impact of loss of myelin, as occurs in diseases such as multiple sclerosis (Coggan et al. 2010). Loss of myelin leads to a slowing of action potential propagation or even action potential failure altogether.

Ion Channel Noise

Noise in the nervous system comes in many different forms (Faisal et al. 2008), with a major source being the stochastic opening and closing of ion channels in neuronal membrane. The thinness of axons makes them vulnerable to this form

of noise. Computational models in which the deterministic ion channel models of Hodgkin and Huxley are replaced by equivalent stochastic models are used to investigate the impact of ion channel “noise” on action potentials (Goldwyn and Shea-Brown 2011).

The standard approach to turning a deterministic model of the action potential, such as the Hodgkin-Huxley model, into an equivalent stochastic model is to treat the ionic conductance in a patch of membrane of a particular ionic species as being a function of the number of open ion channels for that species. Firstly, the dynamics of conductance change in the deterministic model can be rewritten in the form of a kinetic scheme, which is interpreted as the concentration of ion channels in different states, one of which is an “open” state and provides the conductance. An example of such a scheme for the potassium conductance in the Hodgkin-Huxley model is.

Now the total conductance for potassium in a patch of membrane is.

$$g_K(v, t) = \gamma_K[n_4]$$

where γ_K is the conductance of a single open potassium channel.

This becomes a stochastic model if the patch of membrane is assumed to contain N ion channels and the rates of the kinetic schemes become transition probabilities between states for individual channels, resulting in continuous-time Markov chain. The stochastic model approaches the deterministic model as N goes to infinity. However, for finite numbers of all ion channels, N , the stochastic model can exhibit significantly different behavior from the deterministic model.

Ion channel numbers in a patch of axon may be such that the variation in membrane potential from the opening and closing of individual ion channels may be apparent, particularly near the threshold of action potential initiation where the number of open ion channels is small (Schneidman et al. 1998). This can lead to stochasticity in the generation of action potentials, as illustrated in Fig. 4.

Axon, Modeling, Fig. 4 Spontaneous generation of action potentials in a stochastic Markov model of a $100 \mu\text{m}^2$ patch of membrane containing 6000 sodium and 1800 potassium channels. Simulation performed using the MATLAB code of Goldwyn and Shea-Brown (2011) as available in ModelDB (accession number 138950)

Fluctuations in ion channel opening can advance or retard action potential initiation and even lead to failures in propagation, though propagation is more reliable than initiation (Faisal and Laughlin 2007). Multiple trials of a stochastic model of axon stimulation by a fluctuating current are shown in Fig. 5.

Simulating the Markov model for all ionic species is computationally demanding. Other ways of incorporating membrane noise, which involve some stochastic description of the noise contribution of channel fluctuations, have been tried and can provide a good approximation to the full Markov description (Goldwyn and Shea-Brown 2011).

Axon Development

A completely different class of model is used to explore the development of axons. A major issue here is how an axon reaches its target nucleus and forms synapses therein. Models of axon guidance make explicit the interaction between extracellular attractive and repulsive cues and intracellular growth mechanisms in the growth cone and trailing axon. This requires modeling some form of extracellular environment that contains physical barriers to axon growth and diffusible or membrane-bound molecules acting as attractive and repulsive cues (Fig. 6). Krottje and van

Axon, Modeling, Fig. 5 Action potential initiation and propagation due to fluctuating current stimulation in a stochastic membrane model of a squid-type axon with 0.2 μm diameter. The topmost row shows the stimulus current. Below, each row contains spike raster plots of

60 repeated trials recorded at equally spaced axonal positions. Data is extracted from 10-s trials (Fig. 1 from Faisal and Laughlin (2007), reproduced with permission according to the Creative Commons Attribution License)

Axon, Modeling,

Fig. 6 Neurite outgrowth in an external environment containing three sources of a diffusible attractive chemical. (Reproduction of Fig. 10.10 from Sterratt et al. (2011), with permission of the authors)

Ooyen (2007) provide a suitable mathematical description of such an environment in the form of partial differential equations (PDEs) and quasi-steady-state approximations solved across a spatial grid. Axons themselves may not play a space-filling role in the environment.

Models concerned with the details of axon growth and branching, on the other hand, need to include the mechanisms of intracellular signaling, the viscoelastic properties of the axon, and the spatial extent of growth cones (Fig. 7).

A

Axon, Modeling, Fig. 7 Axonal pathfinding. Detection of chemoattractants in the external environment by filopodia produces tension on the growth cone in particular directions. The growth cone will turn toward and grow along the dominant direction. If similar forces are exerted

on opposite sides of the cone, the tension may be enough to split the cone into two, leading to the formation of daughter branches (Reproduction of Fig. 3 from Graham and van Ooyen (2006), with permission according to the Creative Commons Attribution License)

Computational simulation environments, including CX3D (Zubler and Douglas 2009) and NETMORPH (Koene et al. 2009), provide facilities for modeling aspects of axonal and dendritic development and the subsequent formation of neural networks. A review of modeling and computer simulation techniques for neuronal development is provided by Graham and van Ooyen (2006).

Balanced State

Lars Schwabe

Department of Computer Science and Electrical Engineering, Adaptive and Regenerative Software Systems, Universität Rostock, Rostock, Germany

Synonyms

[High-conductance state](#)

Definition

The balanced state of neurons is characterized by a high value of the total membrane conductance caused by synaptic inputs. It is the state of cortical neurons in vivo in awake animals, and it is due to massive excitatory and inhibitory inputs that almost cancel out. In this state, the responses are driven by fluctuations (possible also due to coincident events) in the input, and due to a greatly reduced effective membrane time constant, the neuron responds rapidly.

Detailed Description

The notion of high-conductance states, and the fact that neurons could integrate differently in such states, was first proposed by modeling studies. A meanwhile classical dichotomy distinguished between two operating modes of neurons: the integrator mode and the coincidence detection mode. In the integrator mode, the postsynaptic neuron is emitting spikes, because it integrates over time the excitatory presynaptic inputs. In the coincidence detection mode, it fires spikes, because many presynaptic excitatory neurons synchronize their excitatory inputs. By changing the time constant of the postsynaptic neuron, one could switch between these two modes: Coincidence detection calls for a short time constant, where the neuron quickly “forgets” previous inputs and needs coincident spikes so that the membrane potential is elevated enough to emit a postsynaptic spike; in the integration mode, the time constant should be longer to allow for summing inputs over time. Cortical neurons *in vivo* are likely to operate in the latter mode, because due to massive excitatory and balanced inhibitory inputs, the effective time constant is very small. This has various consequences for cortical computations at both the single-neuron and network levels, which are now addressed in greater detail, over the observation of a “high-conductance state” in recapitulated.

Empirical Evidence for a “High-Conductance State”

It is well known to physiologists that neurons in anesthetized animals often appear during intracellular recordings as if they operate in two distinct states, namely a so-called “up” state and a “down” state. In the “up” state, the neurons are depolarized and can fire action potentials, which are irregular as observed in extracellular recordings in awake animals. In the “down” state the neurons are hyperpolarized and emit no spikes. How do these two states emerge? The detailed mechanisms are still under investigation, but experiments revealed that the “down” state can

be much more easily manipulated via current injections than the “up” state. The lack of strong effects in the “up” state is consistent with a very high membrane conductance. A plausible explanation of this approximately 2–3 times increase of conductance relative to the resting leak conductance is to assume it as due to synaptic inputs.

Consequences for Single-Neuron Computations

In 1994 Shadlen and Newsome explored the idea that excitatory and inhibitory synaptic inputs might be balanced and keep the membrane potential close to, but below, the firing threshold (Shadlen and Newsome 1994). In this scenario the neuron can still respond, because fluctuations can push the membrane potential above a threshold. Simulation studies showed that in this regime, the neural responses are much more irregular compared to a non-balanced scenario with little or no inhibition, i.e., when strong excitation drives the responses. For neuronal models this means that neurons in a balanced state are best described with stochastic formalisms (Tuckwell 1988).

Given that neurons in the balanced state are sensitive to fluctuations in the inputs, they could also detect *changes* in such fluctuations. Of particular interest have been those brought about by changing correlations between presynaptic excitatory, inhibitory, or between excitatory and inhibitory spikes (Salinas and Sejnowski 2000). Interestingly, such correlations could change without affecting the average of the inputs. For neuronal modeling this is important, because it calls for stochastic models beyond simplistic rate-based descriptions. The fluctuations of balanced inputs have been implicated in changing the gain of neurons. Such gain modulations have been described as a physiological signature of attentional top-down modulations. Chance et al. (2002) have shown the feasibility of this mechanism using modeling and dynamic-clamp (Sharp et al. 1992), but *in vivo* tests of this hypothesis remain technically too challenging.

Another consequence of the balanced state is that responses to inputs can be very rapid as

pointed out already in 1975 by Barrett (1975). This can be demonstrated using the simple RC circuit model of the subthreshold membrane potential dynamics: Let us consider a leaky integrator, modeled as an RC circuit, with a time constant $\tau = RC = C/g$, where R is the membrane resistance (and $g = 1/R$ the conductance) and C is the membrane capacitance. The dynamics of membrane potential V are given by.

$$C \frac{dV}{dt} = -gV + g_{\text{AMPA}}(t)(E_{\text{AMPA}} - V) + g_{\text{GABA}}(t)(E_{\text{GABA}} - V)$$

where $g_{\text{AMPA}}(t)$ and $g_{\text{GABA}}(t)$ are the excitatory and inhibitory synaptic conductances (with reversal potentials E_{AMPA} and E_{GABA}) due to approximately balanced presynaptic inputs, i.e., the resulting currents cancel each other at a certain subthreshold voltage. These synaptic conductances are time dependent due to the different arrivals of spikes at the synapses and the kinetics of synaptic transmission. Averaging these conductances over time yields g_{AMPA} and g_{GABA} . Setting $\frac{dV}{dt} = 0$ and solving for the effective time constant τ_{eff} shows that.

$$\tau_{\text{eff}} = \frac{C}{g + g_{\text{AMPA}} + g_{\text{GABA}}} < \frac{C}{g}.$$

Thus, with increasing synaptic conductance, the neuron responds faster. This may be of particular relevance in sensory systems with high-frequency inputs, because in a non-balanced state, the neuron could not lock to such inputs.

Such a high-conductance state also affects the integration of dendritic signals. In line with Rall's classical works (Rall 1964), Barrett also suggests a location-dependence of the impact of dendritic inputs onto the somatic membrane potential. He emphasized the role of synaptic background activity, which would decrease the resistance and further reduce the impact of distal dendritic inputs. Experiments showed, however, that the dendritic inputs are approximately location-independent (Magee 2000). This observation could be a natural consequence of the massive synaptic inputs onto

active excitable dendrites in the balanced state, i.e., dendrites that support the local initiation of spikes (London and Häusser 2005). Rudolph and Destexhe have shown in simulation studies (Rudolph and Destexhe 2003) that the decreased impact with increasing distance from the soma predicted by Rall and Barrett could be balanced by an increased likelihood of evoking a dendritic spike as the input resistance increases with distance from the soma.

Consequences for Network-Based Computations

While single-neuron modeling studies usually assume background inputs with certain properties such as balanced inputs, network models need to explicitly account for them. In 1996 van Vreeswijk and Sompolinsky (1996) showed that sparsely connected recurrent networks with strong but balanced excitation and inhibition naturally lead to the temporally irregular spiking patterns observed in awake animals. One may wonder how such a tight balance between excitation and inhibition required by network models could be realized in cortical networks, given that local inhibitory interneurons are far less numerous than the excitatory neurons. Despite their lower absolute number, inhibitory neurons are often reported to have higher firing rates. Moreover, their synapses onto postsynaptic targets show much less short-term depression than excitatory synapses. In combination, this could make the recurrent inhibition much stronger than evident by their lower absolute number.

It is known that blocking inhibition causes the cortex to become epileptic (Dichter and Ayala 1987), and already in 1975 Sillito showed that reducing inhibition lets sensory neurons (in primary visual cortex, V1) lose their orientation selectivity (Sillito 1975). This further supports the notion that the balanced state is the natural cortical state of awake animals. Experimental studies later investigated in greater detail the potential network mechanisms underlying the spike responses in vivo using paired recordings. For example, Okun and Lampl showed in 2008 via simultaneous intracellular recordings of pairs

of nearby neurons in rat somatosensory cortex (Okun and Lampl 2008) that the excitatory and inhibitory inputs covary in strength and time. They found this covariation during both the spontaneous “resting-state” activity and during sensory stimulation. Mariño et al. (2005) performed intracellular recordings in vivo in V1 and showed that such a covariation in space could explain the experimentally observed invariance of the orientation tuning with location in the orientation map of V1. The balanced state as observed in single neurons may also have large-scale macroscopic correlates, namely, the spontaneously occurring states reported during resting-state activity in V1 (Kenet et al. 2003). From a modeling perspective, it is worth mentioning that such macroscopic phenomena can be simulated and analyzed using rate model (Blumenfeld et al. 2006).

Discussion and Future Directions

Meanwhile, the balanced state is accepted in the community as the state that characterizes cortical neurons in vivo. Many studies have investigated how it affects single-neuron computations. Other studies have developed self-consistent network models that reproduce the balanced state. Experimental tests of model predictions appeared in the literature with quite some delay relative to the modeling studies. This is not a surprise, because direct empirical evidence for the balanced state is technically very hard to obtain, as it calls for intracellular multiunit recordings of connected neurons in vivo. Future modeling studies should respect this and aim at specific predictions for easier to access macroscopic observables. Future modeling studies could also investigate how adaptation at various timescales affects the balance between excitation and inhibition. Given that cortical networks seem to be exquisitely balanced, even small perturbations could have major impacts. The role of inhibitory plasticity in maintaining the balanced state has been addressed in first modeling studies (Vogels et al. 2012). Exploring how a certain adaptation or learning mechanism behaves in the balanced state in vivo is now becoming a necessity for all modeling

studies of adaptation, learning, and cortical computation. Finally, one may need to address explicitly the energetic costs of the balanced state. Are the potential benefits, from a normative point of view, really worth all the energy the brain is investing into maintaining this mode of operation? It could be that the most fascinating properties of the balanced state that warrant this investment are still to be discovered.

Baroreceptor Reflex

► Baroreflex Models

Baroreflex Models

Yaroslav Molkov

Department of Mathematical Sciences, Indiana University – Purdue University Indianapolis, Indianapolis, IN, USA

Synonyms

[Baroreceptor reflex](#)

Definition

Blood pressure is controlled by several feedback mechanisms. The fastest one baroreceptor reflex (baroreflex) can be defined as the biological neural control system responsible for the **short-term** blood pressure regulation.

From modeling perspective the baroreflex feedback control system consists of three parts (Fig. 1):

- The afferent part where the arterial pressure is being read out, transduced, and supplied
- The central nervous system (CNS) where this input is processed and converted to the sympathetic and parasympathetic nerve activities
- The effector organs that respond to sympathetic and parasympathetic tones by adjusting

heart rate, contractility, vascular resistance, and a number of other physiological parameters

The afferent part is represented by baroreceptors, mechanoreceptors located in the great arteries, heart, and pulmonary vasculature, that transduce arterial pressure into action potential trains. Baroreceptors provide input to second-order neurons in nucleus tractus solitarius (NTS) located in the lower brainstem. Via a network of interneurons, the second-order barosensitive neurons provide an excitatory input to cardiac vagal motoneurons (CVM) in nucleus ambiguus (NA) and dorsal motor nucleus of vagus (DMNX) and inhibit the pre-sympathetic neurons in rostral ventrolateral medulla (RVLM). CVMs and pre-sympathetic RVLM neurons define parasympathetic (para-SNA) and sympathetic (SNA) nerve activities, respectively. **Baroreflex models** are aimed to quantify para-SNA and SNA reflex responses to sharp changes in arterial BP and, thus, attempt to describe the neural part of the system.

Closed-loop models of cardiovascular system usually include a baroreflex compartment, and a number of effector organs controlled by sympathetic and parasympathetic activities (Fig. 2).

Detailed Description

Deviations in blood pressure (BP) and blood volume are sensed in cardiovascular system by **baroreceptors**, mechanosensitive nerve endings activated by vascular or cardiac distension (Fig. 2). **Arterial baroreceptors** (located in the aortic arch and the carotid sinuses, see Fig. 1) increase their activity when BP rises, and reduce it if BP lowers. **Cardiopulmonary baroreceptors** in the heart, vena cava and pulmonary vasculature are aimed to sense central blood volume, and are sometimes called *volume receptors* or *low-pressure receptors*.

The afferent activity from arterial baroreceptors is sent to the medullary brainstem area called nucleus tractus solitarius (NTS) through glossopharyngeal nerve (from carotid sinus baroreceptors) and vagus nerve (from aortic arch) that

Baroreflex Models, Fig. 2 Baroreflex negative feedback control of arterial blood pressure (*BP*) (From Chapleau 2011 with permission)

together are known as the **buffer nerves**. In the NTS this information is processed by an intricate network of interneurons that control efferent para-sympathetic (para-SNA) and sympathetic (SNA) nerve activities and release of antidiuretic peptide vasopressin (AVP) (see Fig. 1). All these

mechanisms in response to changes in the arterial BP cause reflexes (Fig. 2) that ultimately push BP in the opposite direction providing a negative feedback control of arterial BP called **arterial baroreflex**. The CNS pathways of cardiopulmonary baroreceptors are similar to that of arterial

ones except their activation has little effect on heart rate (HR) which is the fastest mechanism of BP control.

Due to complexity of the system, modeling studies usually focus on a particular aspect depending on phenomena considered while using simplified description of other compartments. Several integrative mathematical models were used to elucidate the role of baroreflex in cardiovascular instabilities, such as heart rate variability and spontaneous fluctuations of the arterial pressure (e.g., Mayer waves).

Pressure-Electrical Transduction

As a result of a change in arterial pressure, the cross-sectional area of the arteries changes leading to mechanical deformation of artery walls. Changes in the membrane strain resulting from the artery wall deformation lead to changes in the conductance of a variety of mechanosensitive ion channels in the sensory terminals of arterial baroreceptors. The cumulative effect of the opening of those channels in response to rise in pressure is an increased inward (depolarizing) current. If the resulting depolarization exceeds certain threshold, baroreceptors start firing action potentials with a rate defined by the magnitude of this current.

In mechanoreceptors variations in membrane strain affect protein conformations and, hence, cause changes in the probabilities for mechanosensitive membrane channels to be in open and close states (Morris 1990). Accordingly, a net inward current flow through mechanosensitive ion channels is often modeled as a nonspecific current with zero reversal potential and Boltzmann-like dependence of the conductance on arterial pressure P :

$$I_{\text{baro}} = \frac{g_{\text{max}}}{1 + \exp(-K(P - P_{1/2}))} (V - E_m)$$

where g_{max} is a maximal conductance of this current, $P_{1/2}$ is half-activation pressure, K defines the sensitivity and E_m is a reversal potential usually accepted 0.

Rose et al. (1995) used a little different approach. Their baroreceptors had a pressure-dependent depolarizing current which was linear above a threshold pressure: $I_{\text{baro}} = K(P - P_{\text{thr}})$ if $P > P_{\text{thr}}$ and $I_{\text{baro}} = 0$ otherwise.

Baroreceptors

Baroreceptor response to changes in arterial BP is very complex, nonlinear, and has multiple time-scales. Rapid jumps in BP lead to much stronger changes of baroreceptor activity than gradual excursions of the same magnitude. Acute hypertension results in a sharp rise in the baroreceptor activity which, however, declines in time if hypertension is maintained. After acute withdrawal from the increased BP, baroreceptors first exhibit reduced activity (post-excitatory depression) which then adapts back to baseline.

In short, the properties of the firing rate of the baroreceptors in response to changing arterial pressure modeling-wise important can be formulated as follows (Ottesen et al. 2004):

- Firing rate increases with BP.
- The response exhibits threshold and saturation.
- Sufficiently fast decreases in pressure cause firing rate to fall below the threshold.
- A step change in pressure causes a step change in firing rate followed by a decay in firing rate (called adaptation or resetting depending on the timescale).
- Response curves are sigmoidal and show asymmetric hysteresis-like behavior.

Conductance-Based Baroreceptor Model

Baroreceptor fibers are divided into two different types, A-type and C-type, depending on whether they are myelinated or not. Schild et al. (1994) performed a thorough study of their electrophysiological properties and developed a conductance-based model of A- and C-type cells based on voltage-clamp recordings in rat nodose sensory neurons (carotid sinus baroreceptors). Their model included two Na^+ currents exhibiting fast and slow tetrodotoxin (TTX)-insensitive kinetics; low- and high-threshold Ca^{2+} currents exhibiting

transient and long-lasting dynamics, respectively; and outward K^+ currents consisting of a delayed-rectifier K^+ current and Ca^{2+} -activated K^+ current. The model also includes extra- and intracellular Ca^{2+} dynamics.

Firing Rate-Based Baroreceptor Model

In Ottesen et al. (2004) a very elegant model is suggested that accounts for major properties of baroreceptor response. His model describes nonlinear responses of a baroreceptor to changes in carotid pressure in terms of a single nonlinear ordinary differential equation:

$$\frac{dn}{dt} = k \cdot \frac{dP_c}{dt} \cdot \frac{n(M-n)}{(M/2)^2} - \frac{n-N}{\tau}$$

where n is the firing rate of the baroreceptor, P_c is the carotid pressure, M is the maximal firing rate, τ is the adaptation time constant, k is a weighting constant, and N denotes the threshold. Instantaneous rate of change of the firing rate is proportional to the time derivative of carotid pressure and to the firing rate itself. Accordingly, the change in firing rate is most sensitive to change in carotid pressure when the value of the firing rate is in the middle of its physiological range $[0, M]$ and almost insensitive near the boundary. This defines the sigmoidal form of the response curve.

Experimental data shows that the adaptation has many different timescales from seconds to hours or even days. As mentioned, baroreceptor fibers are divided into different types, fast A and slow C fibers, in accordance to whether they are myelinated or not. The fast A fibers are further divided into subtypes. It was suggested that different types of baroreceptors can be characterized by significantly different adaptation time constants (Ottesen and Olufsen 2011). In this case their integrated activity n is calculated as

$$n = N + \sum_{i=1}^K \Delta n_i$$

where Δn_i is a deviation of the firing rate of the type i baroreceptor from the threshold value N , driven by a nonlinear differential equation similar to the above:

$$\frac{d}{dt} \Delta n_i = k_i \cdot \frac{dP_c}{dt} \cdot \frac{n(M-n)}{(M/2)^2} - \frac{1}{\tau_i} \Delta n_i$$

and K is a number of different baroreceptor types. Ottesen and Olufsen (2011) show the example where a satisfactory fit of the experimentally observed responses of the firing rate to a step input pressure requires $K = 3$ types of baroreceptors with time constants $\tau_1 \approx 0.5$, $\tau_2 \approx 10$, and $\tau_3 \approx 3000$ s.

Nucleus Tractus Solitarius (NTS)

Baroreceptors map the spatial pressure distribution onto the inputs to the second-order neurons in the NTS. One of the puzzles of the identified baroreflex-related neurons in NTS is that in spite of receiving direct inputs from the first-order neurons, their activity does not have any frequency component corresponding to cardiac frequency. Somehow they do not respond to each heartbeat by performing a “low-pass filtration” of their inputs.

Rogers et al. (2000) suggested that this property can be concerned either with specific biophysical properties of NTS baroreceptors (Fig. 3) or with specific interactions in the NTS network of second-order interneurons (Fig. 4). By analyzing the responses of the second-order NTS neurons to induced blood pressure pulses, they have noticed that barosensitive second-order NTS neurons respond to blood pressure changes with a burst of activity whose frequency is much lower than the frequency of cardiac cycle, and the activity of these neurons is inhibited just before and after the bursts. Using these observations they developed a series of mathematical models of early stages of baroreflex based on the intrinsic cell properties and network mechanisms.

Intrinsic Properties-Based Model

Individual NTS neurons were modeled using a single-compartment description in the Hodgkin–Huxley formalism. The most important feature of

their individual neuron model was that in addition to ionic channels responsible for spiking behavior (like fast sodium and potassium delayed rectifier channels), they incorporated

mechanisms for the response adaptation (A-type potassium, calcium-dependent potassium, and low threshold calcium currents). This mechanism together with intracellular calcium dynamics allowed them to reproduce several important properties of the second-order baroreceptors previously identified experimentally: (1) frequency adaptation in the cell's response to a step stimulus; (2) sensitivity to the rate of change of input; and (3) the lack of response to each pulse of a pulsatile stimulus; however, if these pulses were imposed on a ramp stimulus, the cell could respond to each pulse.

Inhibition-Based Model

Barosensitive NTS neurons show a variety of responses to both buffer nerve shock and arterial pressure increases. These neurons may respond to buffer nerve shock with excitation (EPSPs), inhibition (IPSP), or an EPSP/IPSP combination. Accordingly, they may be excited, inhibited, or responded with an extinction response to increases in arterial pressure. To account for a variety of responses, Rogers et al. (2000) proposed a populational model of barosensitive NTS neurons based on specific neural circuitry. In this case they also used Hodgkin-Huxley-based description but without Ca^{2+} and $\text{K}(\text{Ca}^{2+})$ conductances. So this model solely relies on the network architecture, rather than on the neurons' biophysical properties.

Baroreflex Models, Fig. 3 Schematic used by Rogers et al. (2000) for NTS model based on specific electrophysiological properties. Arterial pressure is transduced by baroreceptors (nodose) according to their pressure thresholds, indicated by shading (*top cell*: highest pressure threshold). All NTS neurons receive input from all baroreceptors. Each input to any given NTS cell is equally weighted. The only difference between the NTS neurons is the total synaptic weight provided by the baroreceptors, which is varied systematically with the top neuron (A) receiving the highest total drive and the bottom neuron (E) receiving the lowest total drive

Baroreflex Models, Fig. 4 Architecture of the model proposed to explain variability of NTS neuronal responses to buffer nerve shock and arterial pressure increases. This model consists of two populations of baroreceptors, type A and type C, that have different pressure thresholds and sensitivities. The two baroreceptor populations provide

input to the excitatory population of second-order NTS neurons. This population sends excitatory inputs to the population of inhibitory neurons (represented by the *shaded circle*), which in turn inhibits the former (Adapted from Rogers et al. 2000 with permission)

Barotopic Hypothesis

Because of the different pressure thresholds, baroreceptors have a distributed sensitivity to BP and its rate of change. “Barotopic” organization hypothesis suggests that individual baroreceptors’ pressure thresholds (below which they are silent) are topically distributed in an interval of the pressures and that each second-order barosensitive neuron receives inputs from the first-order ones, whose thresholds lie in a definite small interval of pressure values.

Rose et al. (1995) used this architecture in their model of baroreflex control of heart rate. The neural portion of their model included baroreceptors, neurons of the nucleus tractus solitarius (NTS), and cardiac vagal motoneurons (CVM) (Fig. 5) all described in Hodgkin–Huxley style.

In addition to basic spiking currents baroreceptors in their model included A-type potassium current responsible for rapid adaptation and a pressure-dependent depolarizing current which was linear above a threshold pressure (see section “Pressure-Electrical Transduction”). Each baroreceptor had its own threshold pressure P_{thr} , and the thresholds had a sigmoidal distribution. Each NTS neuron received excitatory inputs from several baroreceptors with close thresholds and projected to several CVMs. The NTS neurons and CVMs had six conductances: sodium, delayed-rectifier potassium, A-type potassium, AHP-type potassium, I-type calcium, leakage conductances,

and intracellular calcium dynamics including pumping and buffering. The CVMs projected to the sinoatrial (SA) node where their action potentials activated an acetylcholine (ACh)-activated inward rectifier K^+ hyperpolarizing current which slowed the depolarization of the node and hence decreased the heart rate. The effect of vagal impulses on the hyperpolarizing current was greater for those arriving later in the cardiac cycle.

Sympathetic and Parasympathetic Activities

Second-order baroreceptors in the NTS through a network of interneurons modulate parasympathetic and sympathetic efferent outputs by exciting cardiac vagal motoneurons (CVM) in NA and DMNX and inhibiting pre-sympathetic neurons of RVLM, respectively. The details of this network are unknown. For the sake of simplicity, NTS is often considered as a source of single excitatory drive that directly activates CVMs. The effect on SNA is mediated by GABAergic interneurons in CVLM that in turn inhibit pre-sympathetic neurons in RVLM. In firing rate-based approach, the parasympathetic and sympathetic activities are usually calculated as ascending and descending sigmoid functions of aggregate NTS output, respectively. Ottesen et al. (2004), for example, suggest the following sigmoids:

Baroreflex Models,
Fig. 5 Architecture of a neural portion of the model by Rose et al. (1995). (Reproduced with permission)

$$n_{\text{sym}}(n) = \frac{1}{1 + (n/n_0)^v}, n_{\text{par}}(n) = 1 - n_{\text{sym}}(n)$$

$$= \frac{1}{1 + (n/n_0)^{-v}}$$

where $n_{\text{sym}}(n)$ and $n_{\text{par}}(n)$ are SNA and para-SNA, respectively, n is NTS output, n_0 is the baseline NTS output with fully adapted baroreceptor activity, and v defines the steepness of the curves.

The parasympathetic output is provided directly by vagal motoneurons, while sympathetic activity is formed by a longer chain of neural structures and involves several neurotransmitter systems. This difference is often taken into account by introducing a time delay in sympathetic response which can constitute up to several seconds. Ottesen and Olufsen (2011), for example, model parasympathetic activity as proportional to the baroreceptor firing rate $n(t)$ and SNA is defined by the delayed version of $n(t)$:

$$n_{\text{par}}(t) = \frac{n(t)}{M}, n_{\text{sym}}(t) = 1 - \frac{n(t - t_d)}{M}$$

where M is the maximal baroreceptor firing rate, and t_d is the time delay.

Respiratory Baroreflex

As mentioned, the classical baroreflex control of sympathetic nerve activity (SNA) operates via the second-order baroreceptor neurons that project to the caudal ventrolateral medulla region (CVLM). Through this path, the baroreceptor activation provides activation of CVLM neurons which in turn inhibit the pre-sympathetic rostral ventrolateral medulla (RVLM) neurons hence lowering both the RVLM activity and SNA. This pathway provides a direct negative SNA reflex response.

Sympathetic activity contains the respiratory modulation, which suggests that sympathetic and respiratory networks interact. Respiratory activity is also known to be modulated by the baroreceptor input. Together these facts imply that there may be another baroreflex pathway mediated by the respiratory neurons.

Baekey et al. (2010) have demonstrated that transient pressure pulses perturb the respiratory

pattern in a phase-dependent manner, and those perturbations strongly depend on the integrity of the pons. The stimuli were delivered during inspiration, post-inspiration, or late expiration. With pons intact, the applied barostimulation had almost no effect on the amplitude and duration (i.e., inspiratory period) of the phrenic bursts even when stimuli were delivered during inspiration. At the same time, these stimuli suppressed or abolished inspiratory modulation of SNA. In contrast, the same stimuli delivered during post-inspiration or late expiration produced an increase in the expiration period and decreased SNA. The barostimulation-evoked prolongation of expiration was greater if stimulation was applied later during the expiratory phase. After pontine transection the barostimulation shortened the apneustic inspiratory burst. In all cases the sympathetic baroreflex-induced lowering of SNA persisted confirming the presence of a direct baroreflex pathway which bypasses the respiratory network.

Based on their experimental findings, Baekey et al. (2010) developed a mathematical model of baroreceptor-respiratory-sympathetic interactions that explained phase-dependent respiratory response to transient barostimulation. One of the implications of their model was that there is indeed a second pathway from baroreceptors to pre-sympathetic neurons in RVLM. This second pathway is mediated by respiratory circuits, specifically by the post-I neurons of BötC. This baroreflex pathway is strongly dependent on the respiratory-sympathetic interactions and needs pons to be intact.

Another interesting implication of their model is that the sympathetic baroreflex gain depends on the respiratory phase, because a subpopulation of NTS second-order baroreceptors is inhibited during inspiration (Fig. 6).

The Role of Cardiopulmonary Baroreceptors

A majority of modeling studies only take into account arterial baroreceptors. However, under certain conditions blood volume regulation provided by cardiopulmonary baroreceptors plays a

Baroreflex Models, Fig. 6 (a) Conceptual model of interaction between respiratory-related activity of the ventral respiratory column (VRC), pontine circuits (PONS), sensory network in the nucleus tractus solitarius (NTS), and rostral and caudal ventrolateral medulla (RVLM/CVLM). The sympathetic baroreceptor reflex operates via two pathways (red solid arrows): one direct pathway includes baroreceptors, 2nd-order barosensitive cells (Baro) in the NTS and CVLM, which inhibits RVLM and SNA; the other pathway routes via the Böttinger complex (BötC) in the VRC, whose post-inspiratory neurons inhibit RVLM and

SNA. Blue dotted arrows represent the effects of VRC and PONS on RVLM providing respiratory modulation of SN activity. (b) The schematic of the computational model by Baekey et al. (2010) showing interactions between different populations of respiratory neurons within major brainstem compartments involved in the control of breathing and sympathetic motor activity (pons, BötC, pre-BötC, rVRG, VLM, and NTS). Each population (shown as a sphere) consists of 20–50 single-compartment neurons described in the Hodgkin–Huxley style (Adapted from Baekey et al. 2010 with permission)

major role in blood pressure control. To understand the interplay between different mechanisms, Ursino (2000) developed a closed-loop mathematical model which included both arterial and cardiopulmonary baroreceptors and four effector components: heart period, systemic peripheral resistance, systemic venous unstressed volume, and heart contractility. He simulated the model to mimic the baroreflex response to mild and severe acute hemorrhages and found that the cardiopulmonary baroreceptors play a significant role in the control of systemic arterial pressure during mild hemorrhages (lower than 3–4 % of the overall blood volume). Under these conditions arterial pressure could be maintained at its normal level solely by cardiopulmonary feedback loop without the intervention of the arterial baroreceptors. During more severe hemorrhages the latter take over the responsibility for pressure control, and the contribution of cardiopulmonary baroreceptors becomes negligible.

Ursino (2000) noticed that according to their model the stability region in the parameter space of the closed-loop system is quite narrow. For

example, an increase in the static gain of the baroreceptors or a decrease in the rate-dependent component may lead to self-sustained oscillations similar to Mayer waves.

Baroreflex and Mayer Waves

Mayer waves are synchronous oscillations in SNA and arterial BP slower than respiratory rhythm. The origin and physiological mechanisms of these oscillations are currently unknown. The fact that Mayer waves are abolished by sinoaortic baroreceptor denervation strongly suggests the involvement of arterial baroreflex in this phenomenon. The baroreflex theory of Mayer waves explains the emergence of self-sustained oscillations in arterial pressure by the instability caused by fixed time delays in the baroreflex (presumably sympathetic) feedback loop (see the review by Julien (2006) and the literature therein cited). Since virtually any system with the delayed feedback is unstable for sufficiently large time delay values, many different models of dynamic

arterial pressure control have succeeded in predicting Mayer waves (Julien 2006). The magnitude of the time delay is the determinant factor of the emerging oscillation frequency. Mayer wave frequency varies significantly between species which suggests that different species should have significantly different time delays in baroreflex feedback loop. In spite of numerous hypotheses suggested, no consistent explanation of this species-to-species variability was yet provided. Another challenge for the baroreceptor theory is the dependence of Mayer wave amplitude on the mean SNA level which the existing models fail to explain.

Basal Ganglia System as an Engine for Exploration

V. Srinivasa Chakravarthy and Pragathi Priyadharsini Balasubramani

Department of Biotechnology, Indian Institute of Technology, Chennai, India

Definition

The basal ganglia (BG) system is a deep brain circuit with wide-ranging brain functions. Exploration refers to the sampling of a variety of behaviors not firmly established within a learned repertoire. While the neural source of variability driving exploration within the subcortex has not been identified, the hypothesis that the indirect pathway of the BG is the subcortical substrate for exploration leads to explanations for how a range of putative BG functions might be performed.

Detailed Description

Reinforcement Learning and the Basal Ganglia

For nearly a century, a certain “mysteriousness” has been attributed to the function of the basal ganglia (BG) system – a deep brain circuit of multiple interconnected nuclei, with rich connections to large parts of the cortex (Kinnier Wilson in his Croonian lectures in 1925, Marsden 1982). The mystique surrounding BG has its roots perhaps in the multifarious functions of this circuit. Action selection, action gating, sequence generation, motor preparation, reinforcement learning, timing, working memory, goal-directed behavior, and exploratory behavior – the list of putative BG functions is long and perhaps, by the current state of knowledge, is also incomplete. Lesions of this circuit can show manifestations in many forms – from simple reaching movements to handwriting, balancing and gait, speech and language function, eye movements, and force generation, in addition to cognitive and affective manifestations. A long

line of neurological (Parkinson's disease, Huntington's disease, athetosis, chronic fatigue syndrome) (DeLong 1990) and neuropsychiatric disorders (schizophrenia, obsessive-compulsive disorder, ADHD, apathy, abulia, insomnia) (Ring and Serra-Mestres 2002) are associated with BG impairment.

In one of the earliest forays into the mystery of the BG, Albin et al. (1989) interpreted BG anatomy to consist of two pathways (Albin et al. 1989) with complementary roles in motor manifestations (Fig. 1). BG consist of several nuclei – striatum (caudate and putamen), globus pallidus externa/interna, subthalamic nucleus, and substantia nigra pars compacta (SNc)/reticulata. The BG circuit as a whole receives extensive inputs from the cortex and projects back to cortex via thalamus. Cortical signals to BG flow along two pathways: the direct pathway (DP) and the indirect pathway (IP). The projections from the

striatum, the input port to BG, to globus pallidus interna (GPi), one of the output ports, constitute the DP. The indirect route which connects the striatum to GPi via globus pallidus externa (GPe) and subthalamic nucleus (STN) is the IP (Alexander and Crutcher 1990). Lesions of DP affecting particularly the projections from the striatum to GPi are associated with hypokinetic disorders (distinguished by a paucity of movement), and lesions of IP produce hyperkinetic disorders like chorea and tremor. These findings led to the thinking that activation of the DP facilitates movement, and hence it became known as the “Go” pathway. Contrarily, IP was dubbed the “NoGo” pathway since its activation typically inhibits movement (Contreras-Vidal and Stelmach 1995).

A need to go beyond the simple Go/NoGo picture of BG function had its seeds in experiments (Houk et al. 1995; Schultz et al. 1997) on the firing properties of mesencephalic dopamine cells. Although activities of dopaminergic cells have been linked to reward sensing for a long time, experiments by Schultz et al. (1997) specifically showed that dopamine neurons of ventral tegmental area (VTA) respond to unconditional rewards (food or juice). When a sensory stimulus (like a sound or a light flash) consistently precedes the appearance of reward such that the stimulus is predictive of the reward, then dopamine cells fire in response to the stimulus and also the reward. Such findings led to the insight that dopamine cell activity is analogous to a quantity known as temporal difference error (TD error) that appears in reinforcement learning (RL) theory – a branch of machine learning (Sutton and Barto 1998). Recognition of the analogy between mesencephalic dopamine signals and TD error signals of RL has inspired a much larger effort to draw parallels between other elements of RL theory and anatomical components of BG. Although the effort to explain various functions of BG using RL concepts is a story in the making, it is believed that RL holds the promise to create a comprehensive theory of BG in the long term (Chakravarthy et al. 2010).

RL theory describes how an agent can learn correct stimulus–response (SR) relationships using reward feedback from the environment.

Basal Ganglia System as an Engine for Exploration, Fig. 1 The schematic showing the direct and indirect pathways of basal ganglia

For a given stimulus, responses that yield rewards are reinforced, while those that result in punishment are attenuated. The problem is often complicated by the fact that rewards come after a delay following the response or even after a whole series of responses. The agent then needs a surrogate to reward, which guides its responses in the intervening period. RL theory proposes the *value* function as such a surrogate; a computational module called the *critic* computes value. (The module that performs actions is known as the *actor*.) Value is defined as the total discounted future reward that an agent expects to receive from a given state. Thus, once the value is known, at any instant, the agent chooses the response or action that brings about the greatest increase in value, a process known as *exploitation*. Sometimes it is desirable for the agent to try out actions that are not optimal, by way of adapting to the changing reward patterns of the real world. This selection of suboptimal actions, typically stochastically, is known as *exploration*. Thus, exploitation and exploration are two key complementary processes, the yin and yang, of RL theory (Sutton and Barto 1998).

The Indirect Pathway and Exploration

In actor/critic (AC) models of BG, the emphasis is often on the respective substrates for the actor and critic components in the striatum (Joel et al. 2002), and the dopamine signal for its role in training the AC components. Thus, though exploitation and exploration are complementary processes, exploitation receives most of the attention. Such omission is perhaps not surprising as even in the AC framework, the actor and critic are recognized explicitly as *modules*, while exploration is a mere *mechanism* obtained by a “noise term” in RL equations. Since variability is ubiquitous in the brain – either arising due to thermal noise or chaotic neural dynamics – the search for a specific substrate for exploration in BG was felt unnecessary.

Experimental evidence particularly from functional neuroimaging seems to support this partial view, with a bias towards cortical substrates over

subcortical ones. In fMRI studies, gamblers were asked to choose between slots that are expected to give highest rewards (“exploit”) and less familiar slots that might turn out to be more profitable (“explore”). The areas in the brain that are preferentially activated during exploitation or exploration are noted (Daw et al. 2006). While substrates for value computations were found in orbitofrontal cortex (Knutson et al. 2001), substrates for exploration were found in anterior frontopolar cortex and intraparietal sulcus (Daw et al. 2006). The anterior cingulate cortex (ACC) is suggested to be involved in balancing between exploitation and exploration (Rushworth and Behrens 2008). Studies by Yoshida and Ishii (2006) found activation in prefrontal cortex and ACC when subjects were exploring a maze (Yoshida and Ishii 2006). In the subcortex, it was suggested that the ventral and dorsal striata correspond to critic and actor, respectively (O’Doherty et al. 2004). Thus, though both cortical and subcortical substrates of exploitation have been discovered, no corresponding subcortical substrates for exploration have been found.

Can there be subcortical substrates for exploration? Stein et al. (1997) showed that decorticated kittens can exhibit exploratory and goal-oriented behavior (Stein et al. 1997). Rats with damaged STN were shown to exhibit perseverative behavior or reduced exploration of new options, with persistent selection of older unrewarding ones (Baunez et al. 2001). When bicuculline, a GABA antagonist, was injected into the anterior GPe of primates, the animals exhibited stereotypic movements, and when it was injected into dorsolateral GPe, the animal produced hyperactivity that included exploratory or searching movements for food (Grabli et al. 2004). Drawing inspiration from the studies of Usher et al. (1999), Doya (2002) suggested a link between norepinephrine levels and the “inverse temperature” parameter which controls exploration in RL literature. It is noteworthy that globus pallidus is reported to have high norepinephrine levels (Russell et al. 1992).

Thus, it appears compelling that the STN–GPe system constituting the IP of BG might be the subcortical substrate for exploratory behavior.

The STN–GPe system and its intriguing oscillatory activity do not seem to occupy a prominent place in AC modeling literature. On the other hand, there is an entire line of modeling work that presents the STN–GPe system as a pacemaker in the brain, in reference to its oscillatory activity (Ring and Serra-Mestres 2002; Willshaw and Li 2002). These oscillations have also been linked to Parkinsonian tremor (Hurtado et al. 1999; Terman et al. 2002). Though the aforementioned STN–GPe models explain the behavioral effects of pathological oscillations, they attribute no role to the oscillations in the RL framework that is thought to govern the processes of BG. Under dopamine-deficient or Parkinsonian conditions, the firing patterns of STN and GPe neurons show dramatically increased correlation without significant increase in firing rate (Bergman et al. 1994; Brown et al. 2001). Since exploration is driven by noise in RL models, a brain region that drives exploration is expected to be a source of noise generated perhaps by complex neural dynamics. Considering the low correlation in STN–GPe under normal conditions, with increased correlation or loss of complexity in pathology, it is plausible that the STN–GPe is a subcortical substrate for exploration.

By an extended application of RL concepts, a comprehensive model of BG can be built in which the exploitative dynamics of the DP can be combined with STN–GPe oscillations that drive exploratory behavior (Chakravarthy et al. 2010). Thus emerges a view that while DP supports exploitation, IP subserves exploration, differing from the classical Go/NoGo view of BG. In a recent modeling study, it was shown that the exploitation (DP) versus exploration (IP) can be reconciled with Go (DP) versus NoGo (IP) view, by inserting a third regime dubbed the *Explore* regime. This regime would correspond to exploration and resides between the classic Go and NoGo regimes (Kalva et al. 2012). A series of BG models based on this view have been developed to account for a wide variety of BG-related motor and cognitive behaviors such as spatial navigation, saccades, reaching, and reward–punishment learning (Sridharan et al. 2006; Chakravarthy et al. 2010; Krishnan

et al. 2011; Kalva et al. 2012; Priyadharsini et al. 2012; Gupta et al. 2013; Muralidharan et al. 2013).

The Basic Model

The intuitive ideas outlined before can be embodied in a simple mathematical model of BG. The framework explicitly represents striatum, STN, GPe and GPi, and DP and IP, to capture the structural aspects of BG, and also models:

- The nigrostriatal dopamine signal as TD error, using it to train corticostriatal connections
- The action of dopamine in switching between DP and IP, via its differential action on the D1 and D2 receptors of striatal medium spiny neurons
- Oscillations in the STN–GPe system
- Value computations in the striatum
- The classical Go (DP) and NoGo (IP) with the added “Explore” behavior.

Striatum

The binary action selection problem consists of choosing between two inputs based on their “salience.” Thus, the input, a 2D vector, I^{ext} , representing the corticostriatal afferents, is presented to the striatum that consists of two 1D layers of sigmoidal neurons representing medium spiny neurons (MSNs) (Fig. 2). The first layer represents neurons that express D1-type dopamine receptors (R), whereas the second layer represents D2R-expressing MSNs. The D1R- and D2R-MSN layers project to GPi and GPe, respectively, and they also receive dopaminergic projections from SNc. Each component of I^{ext} is uniquely connected to one neuron each in D1 and D2 layers. The dopamine signal (δ) controls the sigmoidal gain of neurons in D1 and D2 layers. Whereas the gain of D1 neurons increases with δ , that of D2 neurons decreases with δ . With such an arrangement, it can be noticed that the DP is selected at higher dopamine levels and the IP at lower levels (Humphries and Gurney 2002; Humphries and Prescott 2010).

Basal Ganglia System as an Engine for Exploration, Fig. 2 The schematic of signal flow in the BG network model

The STN–GPe System

STN and GPe form a loop with excitatory projections from STN to GPe and inhibitory projections in the reverse direction. Excitatory/inhibitory pairs of neuronal pools are known to exhibit limit cycle oscillations (Gillies et al. 2002). The STN and GPe system receives two inputs: the inhibitory (GABAergic) projection from D2R MSNs of striatum to GPe and the excitatory (glutamatergic) cortical input via the hyperdirect pathway to STN. Several factors elicit oscillations in a STN–GPe neuron pair.

1. Increased striatal input to GPe: This property is corroborated by electrophysiological data from Bergman et al. (1994). Kravitz et al. (2010) observed that increased firing of D2R-MSNs in the striatum induce a state similar to Parkinson’s, with motor symptoms like freezing, bradykinesia, and difficulty in movement initiation (Kravitz et al. 2010).

2. Increasing cortical input to STN: Electrophysiological studies show that ablation of cortical areas that project to STN largely abolished low-frequency oscillations in STN–GPe (Magill et al. 2001).
3. Reducing dopamine levels in STN–GPe: Organotypic culture studies show that the STN–GPe system exhibits low-frequency oscillations under dopamine-deficient conditions as in that of Parkinson’s disease (Plenz and Kital 1999). STN and GPe oscillations seem to be triggered by the effect of dopamine loss on D2R which strengthens the STN–GPe coupling (Steiner and Tseng 2010).

Now consider a network model of the STN–GPe system in which STN and GPe layers have equal number of neurons with each STN neuron uniquely connected bidirectionally to a GPe neuron. Assume that both STN and GPe have complete internal connectivity with all connections within a nucleus having the same strength: ϵ_s for STN, ϵ_g for GPe; the one-to-one common connection strength for STN $\rightarrow$ GPe is w_{sg} and that of GPe $\rightarrow$ STN is w_{gs} . With $(\epsilon = \epsilon_s = -\epsilon_g)$ and $(w = w_{sg} = -w_{gs})$ and searching the (ϵ, w) space for finding the oscillatory behavior of the STN–GPe system, simulations show that for strong connections between STN and GPe (w) and weak lateral connections (ϵ), the network exhibits oscillations (Fig. 3) with poor correlation between the STN–GPe neuronal activity (Fig. 4).

If the STN–GPe system is to serve as a source of exploration, a high spatiotemporal complexity in STN activity manifested in the form of low pair-wise correlations among neurons is expected. The Figures 3 and 4 also illustrate the ability of ϵ_s to control correlation within STN and show that ϵ_s can be used to control the exploration in the BG model.

GPe

GPe combines the GABAergic striatal output via DP with glutamatergic STN output from IP. There is evidence that this combination of DP and IP outflows in GPi is modulated by dopamine projections to GPi. When D1R in GPi, primarily located on the GABAergic striato-pallidal axonal

Basal Ganglia System as an Engine for Exploration, Fig. 3 The regions of parameter space (ϵ , w) over which probability of oscillations in (a) STN and (b) GPe is depicted (averaged over 50 trials)

Basal Ganglia System as an Engine for Exploration, Fig. 4 Correlations within (a) STN and (b) GPe over the parameter space (ϵ , w) averaged for 50 instances. For given

values of parameter pair (ϵ , w), correlation is calculated only when there is at least 1 oscillating neuron in the case of STN for (a) and GPe for (b)

projections, is activated, firing levels of GPi neurons are reduced (Kliem et al. 2007). Since DIRs are activated at increased dopamine levels, the facilitation of the DP outflow over IP at higher dopamine levels is consistent with the nature of switching facilitated by dopamine in the striatum.

Action Selection in Thalamus

If the primary function of the BG circuit is action selection, where in the circuit is the precise site of such selection? If action salience is computed in the striatum and STN–GPe provides exploration, action selection could be happening downstream in GPi or

in the thalamic nuclei receiving afferents from GPi. The competitive dynamics of neurons of thalamic reticular complex makes them ideally suited for implementing action selection (Humphries and Gurney 2002). During binary action selection in the model, the GPi outputs to thalamus converge on two neurons that represent the two action alternatives. These two thalamic neurons integrate the GPi inputs through time: the one that crosses a preset threshold first wins the competition, while the second neuron is reset immediately. Accordingly, if $x_i^{Thal}(t) > x_{th}$ for $i (= 1, 2)$ at time t , then the states of all the other thalamic neurons

immediately reset when “ i ”th action being selected is expressed by $x_j^{Thal}(t) = 0; j \neq i$. If all $x_i^{Thal}(t)$ fail to reach x_{th} , no action is selected.

Simulation Experiments

Binary Action Selection

Salience-based action selection is considered to be one of the primary functions of BG (Redgrave et al. 1999; Gurney et al. 2001). Consider a *binary action selection* problem. The corticostriatal input, I_i^{ext} with $i = 1, 2$, represents two possible actions, and the components of I_i^{ext} represent action salencies. The selected action is denoted by the winning neuron in the thalamus. Due to the complex dynamics of the STN–GPe system, it is not necessary that the winning action is always the one with greater salience. There could be three possible outcomes:

“Go” – winning neuron has greater salience.

“Explore” – winning neuron has lesser salience.

“NoGo” – no winner and therefore no action selection.

Now consider the effect of δ (dopamine) in determining the type of action selection: When the network depicted in Fig. 2 is simulated with the STN–GPe system exhibiting uncorrelated oscillations, a new Explore regime in addition to the classical Go and NoGo regimes (Fig. 5b) can be observed. This is consistent with the classical picture of selecting the Go regime with high probability for large δ and the NoGo for small δ . In addition, the Explore regime is also selected with the probability maximized for moderate δ (Fig. 5a). This Go/Explore/NoGo profile is called the GEN profile.

The notion that higher correlations (caused by higher ϵ_s) among STN neurons result in weaker exploration is depicted by the GEN profiles of Fig. 6a, b, c. Note the progressive reduction in the Explore regime with increasing ϵ_s (Fig. 6).

Modeling the N-Armed Bandit Problem

In the n -armed bandit problem, a generalization of the binary action selection problem, the setup consists of n slot machines each delivering a

fixed reward (deterministically or probabilistically) on selection. The objective is to maximize the total reward received by the agent. Additional features that need to be added to the binary action selection for simulating the n -armed bandit problem are (1) value computation in the striatum, (2) feedback of previous action to the striatum, and (3) resolving the nigrostriatal signal into two dopamine signals – δ_{TD} and δ_V .

If x denotes the action selected ($x_i = 1$, if the i th arm is selected; $x_j = 0$ for $j \sim i$), the action value is computed as

$$V = \sum_{i=1}^n w_i x_i \quad (1)$$

where w_i denote the corticostriatal weights. Instantaneous output error, δ_{TD} , is defined as

$$\delta_{TD} = r - V \quad (2)$$

where r is the reward. Note that δ_{TD} in Eq. 2 above is a special case of the more general temporal difference (TD) error (Eq. 3) in RL,

$$\delta_{TD} = r(t) + \gamma V(t+1) - V(t) \quad (3)$$

that arises when $\gamma = 0$.

This δ_{TD} is used to update the corticostriatal connections as

$$\Delta w_i = \eta \delta_{TD} x_i \quad (4)$$

In addition to δ_{TD} , δ_V is introduced as a similar yet novel quantity representing the temporal gradient of value function and is expressed as

$$\delta_V(t) = V(t) - V(t-1) \quad (5)$$

The difference between *TD error* (Eqs. 2 and 3) and *value gradient* (Eq. 5) is as follows. While TD error controls learning of corticostriatal weights (Eq. 4), value gradient controls the gain of D1R- and D2R-MSNs. D1R-MSNs are modeled to be activated at higher δ_V and D2R-MSNs at lower levels. Thus, δ_V controls exploration by determining the relative contributions of DP or IP.

Basal Ganglia System as an Engine for Exploration, Fig. 5

(a) Probability of selection of Go/Explore/NoGo; (b) schematic: Go–Explore–NoGo (*GEN*) regime selection for higher–intermediate–lower values of δ , respectively

Basal Ganglia System as an Engine for Exploration, Fig. 6 Probability of selection of Go/Explore/NoGo regimes as a function of δ : (a) for $\epsilon_s = 0.001$, (b) for $\epsilon_s = 0.05$, (c) for $\epsilon_s = 0.95$

A large positive δ_v implies a large increase in value, which therefore recommends selection of the same action next time (Go), since the contribution of DP to GPi dominates that of STN. A large negative δ_v implies a large reduction in value, suggesting exploration for new actions.

Basal Ganglia System as an Engine for Exploration, Fig. 7 The mean reward versus iterations obtained with (a) different ϵ_s using the BG network model and (b)

different ϵ values using ϵ -greedy policy, for a five-armed bandit task averaged for 500 trials

Since the IP is selected for strong negative δ_v , IP contribution dominates that of DP at GPi, thereby suppressing action (NoGo). For small magnitudes of δ_v , DP is still reduced, and driven by the complex dynamics of STN, a random action is selected next time (Explore).

Figure 7a shows the change in value function with time for the above model applied to a five-armed bandit problem. The rewards are generated by the following distribution: $r_i = i/n + A \cdot v$, where r_i is the reward of the i th arm, v is a random variable uniformly distributed over $[0, 1]$, and $A = 0.3$. Note the effect of the strength of STN lateral connection, ϵ_s , on the growth of value function. For small ϵ_s ($= 0.0145$), value increases rapidly but settles at a lower value. For large ϵ_s ($= 0.0475$), value rises slowly, but for moderate ϵ_s ($= 0.0305$), it rises slower than the previous case but settles at a level higher than two previous cases. In this respect, the effect of ϵ_s on action selection seems to be analogous to that of the ϵ parameter in ϵ -greedy methods used in RL (Fig. 7b). The parameter ϵ , usually a small positive number, refers to the probability with which a nonoptimal action is selected (Sutton and Barto 1998).

Climbing Value Gradient Using δV

It can be observed from the network model used for the n -armed bandit problem that the value function increases gradually when the action selected is iterated through the loop (thalamo-striatal) in Fig. 2. Thus, the network dynamics implements hill-climbing over the value function, which is a form of stochastic hill-climbing, thanks to the complex dynamics of STN-GPe system. In fact, the aforementioned effect of δ_v on value change (by selecting the previous/random/no action for large positive/moderate/large negative values of δ_v , respectively) is strongly reminiscent of simulated annealing – a form of stochastic optimization (Kirkpatrick et al. 1983). It is noted that the BG model exhibits three behaviors depending on dopamine: (1) Go regime (“repeat the previous action”) for large positive δ_v , (2) Explore regime (“try random actions”) for intermediate values of δ_v , and (3) NoGo regime (“no action”) for large negative values of δ_v . These regimes inspire a simple mechanism of hill-climbing in continuous action spaces as follows.

Let $V(x)$ be value function, x be n -dimensional state vector ($x \in S$, where $S \subset \mathbb{R}^n$), $\delta_v = V(t) - V$

($t - 1$), and $\Delta x = x(t) - x(t - 1)$. Δx is then updated by the following equations:

$$\begin{aligned} &\text{if } (\delta_v > D_{hi}) \\ &\Delta x(t+1) = \Delta x(t) - \text{"Go"} \text{ (a)} \\ &\text{elseif } (\delta_v > D_{lo} \wedge \delta_v(t) \leq D_{hi}) \\ &\Delta x(t+1) = \phi - \text{"Explore"} \text{ (b)} \\ &\text{else } (\delta_v \leq D_{lo}) \\ &\Delta x(t+1) = 0 = \text{"NoGo"} \text{ (c)} \end{aligned} \quad (6)$$

where $D_{hi} > 0$, $D_{lo} < 0$, and Φ is a random vector whose each component, Φ_i , is given by Eq. 7:

$$\phi_i = G(0, 1) \exp(-\delta_v^2 / \sigma^2) \quad (7)$$

where $G(0,1)$ is a Gaussian random variable with mean 0 and standard deviation 1. The last Eq. 6c seems redundant as there is no state update in that case. It can be altered by substituting 0 in Eq. 6c with $-\Delta x(t)$. Now in NoGo regime, the state x is updated in an opposite direction compared to the previous update. The Eq. 6a, b, c may be expressed in modified form as follows:

$$\begin{aligned} &\text{if } (\delta_v > D_{hi}) \\ &\Delta x(t+1) = \Delta x(t) - \text{"Go"} \text{ (a)} \\ &\text{elseif } (\delta_v > D_{lo} \wedge \delta_v(t) \leq D_{hi}) \\ &\Delta x(t+1) = \phi - \text{"Explore"} \text{ (b)} \\ &\text{else } (\delta_v \leq D_{lo}) \\ &\Delta x(t+1) = -\Delta x(t) = \text{"NoGo"} \text{ (c)} \end{aligned} \quad (8)$$

In Eq. 8 above, the Go, Explore, and NoGo regimes are depicted as discrete, disjoint regimes demarcated by thresholds $-D_{hi}$ and D_{lo} . But the regimes observed in the GEN profile obtained from binary action selection problem are not disjoint; their probability distributions as a function of δ_v overlap (Fig. 5). This inspires a combination of Eq. 8a, b, c into a single update equation where the three regimes smoothly overlap as follows:

$$\begin{aligned} \Delta x(t+1) &= \log \text{sig}(k_3(\delta_v(t) - D_{hi})) \Delta x(t) \\ &+ \psi \exp(-\delta_v^2(t) / \sigma_E^2) \\ &- \log \text{sig}(k_4(\delta_v(t) - D_{lo})) \Delta x(t) \end{aligned} \quad (9)$$

where $\text{logsig}(x) = 1/(1 + \exp(-x))$. Thus, Eq. 9 describes a map between the current state update

($\Delta x(t)$) to the next state update ($\Delta x(t+1)$). $\Delta x(t+1)$ is nearly in the same direction as $\Delta x(t)$ for large positive δ_v and is nearly in the same direction as $-\Delta x(t)$ for large negative δ_v ; $\Delta x(t+1)$ is random for the intermediate values of δ_v . Note that the map of Eq. 9 is stochastic due to the middle term on the right-hand side.

Equation 9, known as the GEN rule, represents an abstract, summarized representation of how BG selects actions based on DA signals. The GEN rule or the approach that it is based on has been applied successfully to model a range of BG functions.

Discussion

Application of RL concepts to BG function (Houk et al. 1995; Schultz et al. 1997; Hollerman and Schultz 1998) sought a revision of the Go/NoGo picture as the models may not have given sufficient attention to exploration – the complementary process to exploitation. The Go/NoGo picture of BG can explain how the BG circuit can learn simple binary action selection using RL, but it is inadequate to know how the BG circuit can solve more challenging RL problems in continuous state and action spaces.

The binary Go/NoGo thinking about BG function is supported by a simplistic interpretation of the functional neurochemistry of the two BG pathways (Albin et al. 1989; Contreras-Vidal and Stelmach 1995). But presence of the feedback from STN to GPe allows the possibility of complex dynamics in the STN–GPe loop, thereby introducing an added complication in our functional understanding of BG pathways. The STN–GPe loop has also been dubbed as the “pacemaker” of BG considering its role in generating pathological oscillations associated with Parkinsonian tremor (Hurtado et al. 1999; Terman et al. 2002). This STN–GPe system is an excitatory–inhibitory pair that is capable of exhibiting oscillations and other forms of complex dynamics (Brunel 2000). The fact that neurons in this system exhibit uncorrelated firing patterns in normal conditions, and highly correlated and synchronized firing under dopamine-deficient pathological conditions, seems to offer

an important clue to the possible role of this circuit in exploration. From the above studies, it can be concluded that the STN–GPe system is in the best position to serve as an explorer, thereby supplying the missing piece in the RL-machinery of BG. Behavioral strategies of reaching, saccades, spatial navigation, gait, and willed action are shown to be better modeled using the above theory as follows.

A model of reaching movements highlighting the role of BG was described in Magdoo et al. (2011), where a neural network representing motor cortex is trained to drive a two-joint arm to a target. The output of the BG that is predominant in early stages of learning is combined with that of motor cortex whose relative contribution grows with learning. The BG dynamics governed by the earlier described GEN rule discovers desired activations which are used by the motor cortex for learning. When the dopamine signal is clamped to reflect dopamine deficiency in Parkinsonian conditions, the model exhibited Parkinsonian features in reaching like bradykinesia, undershoot, and tremor.

The idea that the DP and IP subserve exploitation and exploration respectively was used in a model of BG on saccade generation (Krishnan et al. 2011) when applied to standard visual search tasks like feature and conjunction search, directional saccades, and sequential saccades. On simulating Parkinsonian conditions by diminished BG output, the model exhibited impaired visual search with longer reaction times – a characteristic symptom in Parkinson’s disease (PD) patients.

The GEN approach (Eqs. 6, 8, and 9) was used to model the relative contributions of BG and hippocampus to spatial navigation (Sukumar et al. 2012). The model combines two navigational system: the cue-based system subserved by BG and the place-based system by hippocampus. The two navigational systems are associated with their respective value functions that are combined by the softmax policy (Sutton and Barto 1998) to select the next move. This model describes the results of an experimental study that investigates competition between cue-based and place-based navigation (Devan and White 1999). Under dopamine-deficient conditions, the

model exhibited longer escape latencies similar to PD-model rats (Miyoshi et al. 2002).

The GEN approach to BG was also applied to model impaired gait patterns in PD (Muralidharan et al. 2013). Studies by Cowie et al. (2010) investigated gait changes, as PD patients walked through a narrow doorway and observed a strong dip in velocity a short distance from the doorway. In the model of Muralidharan et al. (2013), the simulated agent passed through the doorway without any significant velocity dip under control conditions and exhibited a significant reduction in velocity close to the doorway under PD conditions.

Clinical literature shows that BG has a role in willed action, and its impairment is seen in conditions of BG lesions or diseases like Parkinson’s disease that affect BG (Mink 2003). Recently it was suggested that the BG circuit amplifies will signals, presumably weak, by a stochastic resonance process (Chakravarthy 2013). This study shows that the GEN policy, which is a combination of deterministic hill-climbing process and a stochastic process, may be reinterpreted as a form of stochastic resonance. Applying the model to a simple reaching task, it was shown that the arm reaches the target with probability close to unity at optimal noise levels. The arm dynamics for subthreshold noise is reminiscent of Parkinsonian akinesia, whereas for superthreshold noise the arm shows uncontrolled movements resembling Parkinsonian dyskinesias.

A perspective that the BG circuit is an exploration engine, carved out of the popular RL approach to BG modeling, can thus be substantiated.

Basal Ganglia: Beta Oscillations

Rafal Bogacz

Department of Computer Science, University of Bristol, Bristol, UK

Definition

Beta oscillations are defined as the oscillations in neural activity with frequencies between 13 and 30 Hz (Fig. 1). In the basal ganglia, the power of

Basal Ganglia: Beta Oscillations, Fig. 1 One second of local field potentials recorded from internal segment of globus pallidus (*top panel*) and subthalamic nucleus (*bottom panel*) from a patient with Parkinson's disease who was off medications. (Reproduced from Brown et al. (2001) with permission)

beta oscillations is significantly increased in Parkinson's disease (Hammond et al. 2007).

Detailed Description

Relationship to Behavior

The power of beta oscillations is reduced prior to and during movements in both the cortex and basal ganglia (see Engel and Fries 2010 for review) and increased during tonic contractions (Baker et al. 1997). Consequently, it has been suggested that beta oscillations are related to maintaining the current body posture (Engel and Fries 2010). The causal influence of beta oscillations on inhibition of movement is suggested by observations that stimulation at beta frequency with transcranial magnetic stimulation (Pogosyan et al. 2009) and with deep-brain stimulation (Chen et al. 2007) results in slower movements.

Relationship with Symptoms

The relationship between beta oscillations and inhibition of movements discussed above suggests that the increased beta power in Parkinson's disease may directly relate to the impaired movements observed in the disease (Brown 2007). This hypothesis is supported by the observation that the power of beta oscillations is reduced by the treatments that alleviate symptoms, namely, dopaminergic medications and high-frequency (>100 Hz) deep-brain stimulation of subthalamic nucleus (STN)

(Hammond et al. 2007). Furthermore, the patients with the best improvement in motor skills due to medications also have the largest reduction in beta power in STN after taking the medications (Kuhn et al. 2006).

Models of the Effects of Beta Oscillations

Simulations demonstrated that the exaggerated oscillatory activity leads to movement difficulties possibly because the thalamic neurons (see Fig. 2) become entrained to the excessively oscillatory input from basal ganglia and are no longer able to transmit sensorimotor signals from the cortex (Rubin and Terman 2004). Additionally, an analysis of neural activity in the external segment of globus pallidus (GPe) using information

theory showed reduced entropy during beta oscillations in rats, suggesting that the beta oscillations limit the amount of information transmitted by the neurons in the basal ganglia (Cruz et al. 2009).

Origin of Beta Oscillations

Parkinson's disease is caused by the death of dopaminergic neurons which project throughout the basal ganglia and modulate synaptic transmission and plasticity. However, the exaggerated beta oscillations do not appear immediately after the death of these neurons, but only several days later (Mallet et al. 2008a). This suggests that the beta oscillations result from the adaptations in the network following the reduced dopamine level.

It is still uncertain which of the changes in the connectivity and the levels of neuronal activity, occurring in Parkinson's disease, trigger beta oscillations. Furthermore, due to the complex connectivity in the cortico-basal-ganglia-thalamic circuit (Fig. 2), it is still unclear in which part of the circuit the beta oscillations are generated. The circuit contains many feedback loops, and it is known that neuronal populations connected in loops can generate oscillations (Tiesinga and Sejnowski 2009).

One of the parts of the circuit which is thought to be critical for generation of Parkinsonian beta oscillations is a sub-circuit composed of STN and GPe (Bevan et al. 2002). Its role is suggested by observations that the beta oscillations are prominent in this network (Mallet et al. 2008b), this sub-circuit was shown to be able to produce slower (delta) oscillations in vitro (Plenz and Kital 1999), and blocking connections between STN and GPe abolishes excessive beta oscillations (Tachibana et al. 2011). Additionally, interactions between the STN-GPe network and cortex are likely to play important role in generating Parkinsonian beta, because the cortex and STN become coherent in the disease (Mallet et al. 2008b) and blocking connections between the cortex and STN abolishes excessive beta oscillations (Tachibana et al. 2011).

Basal Ganglia: Beta Oscillations, Fig. 2 Subset of connectivity in the cortico-basal-ganglia-thalamic circuit. Black rectangles denote brain structures, and the rectangle labeled “Output” denotes the output nuclei of the basal ganglia comprised of the internal segment of globus pallidus and substantia nigra pars reticulata. Green arrows and red lines with circles denote excitatory and inhibitory connections, respectively. Blue dashed contours indicate sub-circuits that have been shown to generate beta oscillations in simulations

Computational Models of Beta Generation

Three sub-circuits containing feedback loops (indicated by blue contours in Fig. 2) have been shown to generate beta oscillation in simulations. First, models of the STN-GPe network were shown to generate beta oscillations (a population-level model: Nevado-Holgado et al. 2010; and a model using integrate-and-fire neurons: Kumar et al. 2011). Mathematical analyses of the population-level model revealed conditions the parameters of the STN-GPe model need to satisfy to generate oscillations (Nevado-Holgado et al. 2010; Pavlides et al. 2012; Passillas-Lepine 2013). Second, a computational model of striatum (using Hodgkin-Huxley neurons: McCarty et al. 2011) has been shown to generate beta oscillations. Third, the beta oscillations have been also observed in simulations of the entire cortico-basal-ganglia circuit (a population-level model: van Albada et al. 2009), and the analysis of the model suggested that the beta oscillations originate in the corticothalamic loop in this model.

Additionally, beta oscillations have been also observed in simulations of the entire cortico-basal-ganglia circuit (using integrate-and-fire neurons: Humphries et al. 2006). Furthermore, oscillations close to the beta range (~ 12 Hz) were generated in a model of a subset of cortico-basal-ganglia circuit (in which firing rates of individual neurons were described: Leblois et al. 2006). The analysis of the model suggested the oscillations were generated in a loop composed of cortex, STN, output nuclei, and thalamus in this model.

Model-Based Data Analysis

Computational models have been used to infer the changes in network structure occurring in Parkinson's disease. Eusebio et al. (2009) fitted a simple damped oscillator to event-related potentials recorded from the cortex of Parkinson's patients after stimulation of STN. They observed that the fitted oscillator had a natural frequency in

the beta range, and the data from patients on medications were described by a model with higher damping parameter than data from patients off medications. Also, the dynamic causal modeling was used to infer from local field potentials the differences in effective connectivity in cortico-basal-ganglia-thalamic circuit between healthy and Parkinsonian rats (Moran et al. 2011), and between patients on and off medications (Marreiros et al. 2013). Both of these studies reported increased effective connectivity between the cortex and STN in the states associated with higher beta power.

Synonyms

[Hypokinesia model](#); [Slowness of movement model](#)

Definition

Bradykinesia is the cardinal symptom of Parkinson's disease (PD). It is related to an abnormal slowness of movement. The causes of PD bradykinesia are not known largely, because there are multiple brain areas and pathways involved from the neuronal degeneration site (dopamine (DA) neurons in substantia nigra pars compacta (SNc) and ventral tegmental area (VTA)) to the muscles (see Fig. 1). Bradykinesia models are mathematical and computational constructs attempting to uncover how information is processed in the affected brain areas and what are the biophysical mechanisms giving rise to the observed slowness of movement in PD bradykinesia.

Detailed Description

Bradykinesia, the hallmark and most disabling symptom of PD, refers to an extreme slowness of movement. In early stages of the disease, PD

Basal Ganglia: Bradykinesia Models, Fig. 1 Brain circuits implicated in PD bradykinesia. (a) Pathways from the substantia nigra pars compacta (SNc) and the ventral tegmental area (VTA) to the striatum and from there to the thalamic nuclei and the frontal cortex through the substantia nigra pars reticulata (SNr) and the globus pallidus

internal segment (GPi). (b) Pathway from the SNc and the VTA to the striatum and from there to the brainstem through the SNr and GPi. (c) Pathway from the SNc/VTA to cortical areas such as the supplementary motor area (SMA), the parietal cortex, and the primary motor cortex (M1) and from there to the spinal cord

patients have difficulties with daily activities such as walking, speaking, or getting in and out of chairs (Gibberd 1986). In the later phases of the disease, the entire movement process becomes increasingly slow and occasionally results in a complete inability to move. Patients must concentrate intensely to overcome the inertia of their limbs even when they are executing the simplest motor tasks. Movement is particularly impaired when novel movements are attempted (Connor and Abbs 1991) or when several movements are combined (Benecke et al. 1986; Lazarus and Stelmach 1992).

Anatomical Overview

Initiation and execution of voluntary movements involve brain areas and pathways. The “motor circuit” originates in the motor areas of the frontal cortex, which activate motor portions of the basal ganglia subcortical structures (striatum (STR), globus pallidus external (GPe) and internal (GPi) segments, the subthalamic nucleus (STN), the substantia nigra pars reticulata (SNr)), and the thalamus and which in turn project back to the frontal motor areas of the cortex. The basal ganglia (BG) structures are implicated in the selection of the most appropriate motor command given the current context. Motor commands from

the frontal motor areas of the cortex (premotor, supplementary, and primary motor areas) activate the corresponding motor spinal centers, which then activate the muscles.

Dopaminergic Pathways

A widespread DAergic innervation from SNc and VTA to BG, thalamus, cortex, and spinal cord exists (Williams and Goldman-Rakic 1998; Bjorklund and Lindvall 1984; Sanchez-Gonzalez et al. 2005; Anaya-Martinez et al. 2006). DA heavily innervates STR and modulates its activity (Gerfen et al. 1990). In addition, DA modulates other BG structures including GPe and GPi segments, STN, and SNr (Rommelfanger and Wichmann 2010).

DAergic neurons also innervate and modulate various thalamic nuclei including the ventrolateral nuclei (motor region) (Sanchez-Gonzalez et al. 2005). In rats a common DA projection exists to GP and the reticularis nucleus of the thalamus (Anaya-Martinez et al. 2006).

DA also innervates the cerebral cortex (Berger et al. 1988; Elsworth et al. 1990; Gaspar et al. 1991, 1992; Scatton et al. 1983; Lewis et al. 1988; Lidow et al. 1989; Williams and Goldman-Rakic 1998). DA afferents are densest in cortical areas 24, 4, 6, and SMA, where they display a trilaminar pattern of distribution, predominating in layers I, IIIa, and V–VI (Berger et al. 1988; Williams and Goldman-Rakic 1998; Elsworth et al. 1990; Gaspar et al. 1991, 1992). In the granular prefrontal (areas 46, 9, 10, 11, 12), parietal (areas 1, 2, 3, 5, 7), temporal (areas 21, 22), and posterior cingulate (area 23) cortices, DA afferents are less dense and show a bilaminar pattern of distribution in the depth of layers I and V–VI (Berger et al. 1988; Gaspar et al. 1991, 1992; Scatton et al. 1983; Lewis et al. 1988; Lidow et al. 1989).

Finally, DA innervates the dorsal (sensory input) and ventral (motor output) horns of the spinal cord (Blessing and Chalmers 1979; Shirouzou et al. 1990; Weil-Fugazza and Godefroy 1993; Takada et al. 1988; Commissiong et al. 1979).

Physiological and Behavioral Phenomena

PD bradykinesia has been linked with the degeneration of dopamine neurons in SNc and VTA.

Bradykinesia manifests only when 80–90% of dopamine neurons die. The degeneration of dopamine neurons leads to a number of changes relevant to bradykinesia in the neuronal, electromyographic (EMG), and movement parameters reported in parkinsonian human and animal brains:

- Increases in background activity (spontaneous firing) of STR and STN cells (Kita and Kita 2011).
- An oscillatory response to motor cortical stimulation of STR cells consisting of an excitation, a long inhibition and a slow excitation (Kita and Kita 2011).
- The latencies of the STR excitations are significantly shorter than in the controls (Kita and Kita 2011).
- An oscillatory response to STR oscillatory stimulation of GPe cells consisting of an early excitation, a short inhibition and a late excitation (Kita and Kita 2011).
- An oscillatory response to motor cortical and GPe oscillatory stimulation of STN cells consisting of either an early and late excitation or a single excitation followed by a very long inhibition (Kita and Kita 2011).
- The latency of the GPe inhibition is decreased in the DA depleted case (6-OHDA), whereas the duration and strength of the late excitation are increased (Kita and Kita 2011).
- An oscillatory pattern of GPi cells consisting of an early excitation and a long inhibition or a pattern consisting of a solo long inhibition (Kita and Kita 2011).
- The duration of the GPi excitation and long inhibition is significantly increased in the DA depleted case (Kita and Kita 2011).
- The peak GPi excitatory activity is reduced in the DA depleted case (Kita and Kita 2011).
- Reduction of peak neuronal activity and rate of development of neuronal discharge in the primary motor cortex and premotor area (Gross et al. 1983; Watts and Mandir 1992).
- Disinhibition of reciprocally tuned cells (Doudet et al. 1990). Reciprocal tuned cells are cells that discharge maximally in one

movement direction but pause their activities in the opposite direction.

- Significant increase in mean duration of neuronal discharge in motor cortex preceding and following onset of movement (Gross et al. 1983; Doudet et al. 1990; Benazzouz et al. 1992).
- Multiple triphasic patterns of muscle activation (Hallett and Khoshbin 1980; Doudet et al. 1990). Triphasic pattern of muscle activation is a characteristic electromyographic (EMG) pattern characterized by alternating bursts of agonist and antagonist muscles. The first agonist burst provides the impulsive force for the movement, whereas the antagonist activity provides the braking force to halt the limb. Sometimes a second agonist burst is needed to bring the limb to the final position. In PD patients multiple such patterns are observed in order for the subjects to complete the movement.
- Reduction in the rate of development and peak amplitude of the first agonist burst of EMG activity (Godaux et al. 1992; Corcos et al. 1996; Hallett and Khoshbin 1980; Doudet et al. 1990; Watts and Mandir 1992; Berardelli et al. 1986).
- Co-contraction of muscle activation (Benazzouz et al. 1992). In PD patients the alternating agonist-antagonist-agonist muscle activation is disrupted resulting in the co-activation of opponent muscle groups.
- Increases in electromechanical delay time (time between the onset of modification of agonist EMG activity and the onset of movement) (Benazzouz et al. 1992; Doudet et al. 1985, 1990).
- Asymmetric increase in acceleration (time from movement onset to peak velocity) and deceleration (time from peak velocity till end of movement) times of a movement.
- Decrease in the peak value of the velocity trace (Godaux et al. 1992; Camarata et al. 1992; Weiss et al. 1996; Benazzouz et al. 1992; Doudet et al. 1985, 1990; Rand et al. 2000).
- Significant increases in movement time (Rand et al. 2000; Weiss et al. 1996; Doudet et al.

1985, 1990; Watts and Mandir 1992; Benazzouz et al. 1992).

Types of Theoretical Models of Bradykinesia

Theoretical models of bradykinesia fall under two major categories:

- Verbal-conceptual models: using informal and natural language, describe the brain areas, pathways, and interactions leading to parkinsonian bradykinesia.
- Mathematical and computational models: using mathematical equations as a language, describe the interactions between the various brain areas involved in movement control and execution in parkinsonian bradykinesia.

Verbal-Conceptual Models

An influential model of basal ganglia intrinsic organization was proposed by Albin and colleagues (1989). In their model, motor cortical areas drive two populations of striatal medium spiny output neurones. Neurones containing substance P and D1-type dopamine receptors comprise the “direct” pathway and make contact with the basal ganglia output nuclei. At the same time, striatal neurones containing enkephalin and D2-type dopamine receptors comprise the “indirect” pathway and contact the output nuclei via relays in the GPe and STN. Connections between the various BG components are topographically ordered (Mink 1996). Some projections such as the striatonigral projection (direct pathway) are more focused, whereas others such as the subthalamo-nigral projection (indirect pathway) are more diffuse (Mink 1996). Basal ganglia output is thought to reflect a balance between these two projections, which is disrupted when dopamine neurons die, resulting in a reduction in transmission through the direct pathway and an increase in transmission through the indirect pathway. Dominance of the indirect pathway leads to an excessive inhibition of the thalamus by the GPi, thus leading to an abnormal slowness of movement (i.e., bradykinesia).

Additional anatomical observations have suggested a more complex intrinsic organization of BG structures:

- Cortical layer V pyramidal neurons excite the striatal medium spiny neurons (MSN) giving rise to the striatopallidal projections (indirect circuit) (Lei et al. 2004).
- Cortical layer III and upper layer IV pyramidal neurons excite striatal MSN in the direct striatonigral circuit (Lei et al. 2004).
- Both populations of striatal output neurones project to the GPe, one exclusively (enkephalin/D2 neurones), the other via collaterals from the fibers innervating the output nuclei (substance P/D1 neurones) (Parent et al. 2000).
- GPe neurones make direct contact with the output nuclei as well as with the STN (Smith et al. 1998).
- GPe projects back to the striatum (Bevan et al. 1998).
- STN is driven by cortical layer V inputs (Monakow et al. 1978; Nambu et al. 1997) and subcortical ones external to the basal ganglia, now known as the “hyperdirect” pathway (Nambu et al. 2002).
- GPe is excited by the cortex-STN projection (Obeso et al. 2008; Kita 2007).

The hyperdirect pathway provides a widespread excitation of the GPi via the STN (Mink 1996) and is considered to suppress thalamic and cortical areas related to both the selection of the most appropriate motor program given the current context and competing programs before movement begins.

These experimental observations extend the original Albin and colleague model (1989) of BG information processing. Some of the mathematical and computational models of the next section attempt to explain how dysfunction of these various interconnected BG structures may lead to bradykinesia.

Mathematical and Computational Models

Cortico-Basal Ganglia-Thalamic Interactions

In line with the Albin and colleagues (1989) and Nambu et al. (2002) models, Contreras-Vidal and Stelmach (1995) introduced a detailed population-based model of basal ganglia-

thalamocortical relations in normal and parkinsonian movements. The model's architecture was based on the direct, indirect, and hyperdirect pathways schema of the basal ganglia. Activation of the direct pathway resulted in activation of thalamocortical motor circuits leading to initiation and modulation of movement, whereas activation of the indirect pathway led to breaking of ongoing movement. Activation of the hyperdirect pathway facilitated rapid movement switching or the prevention of movement release. The model showed that loss of striatal DA as it occurs in PD leads to an imbalance in the neurotransmitter dynamics in the direct and indirect pathways, producing smaller than normal BG output signals. In turn these output signals activate insufficiently otherwise normally functioning motor cortical and spinal sites and produce weak and slow movements.

Moroney and colleagues (2008) extended the previous model to investigate the factors that contribute to the slowness of movements of PD patients when they perform simple and complex voluntary movements. Excessive dopamine depletion in the striatum and loss of spatial segregation of neuronal populations operating as functionally independent modules somatotopically mapping particular body parts contribute to a slowness of movement and to a reduced ability to suppress unwanted movements. They further showed that the therapeutic effects of deep brain stimulation (DBS) in STN result from stimulation-induced inhibition of STN, partial synaptic failure of efferent projections, or excitation of inhibitory afferent axons.

DBS is an effective treatment of PD. Chronic high frequency DBS in STN or GPi reduces motor PD symptoms including bradykinesia, although the therapeutic mechanisms of DBS are not fully understood. Recent computational studies have focused on deciphering these mechanisms on BG nuclei. Johnson et al. (2012) investigated which BG neuronal pathways when modulated with high frequency stimulation best correlated with improvement in motor symptoms (bradykinesia and rigidity). Their model predicted that stimulation of a combination of sensorimotor axons within and near the globus pallidus (specifically at the medial medullary lamina) can

have the most beneficial effects on PD bradykinesia. In contrast, improvements in PD rigidity correlated more strongly with the activation of less than 10% of neuronal fibers in internal capsule (IC). Recently, Kumaravelu and colleagues (2016) computationally investigated the effectiveness of different frequencies of STN-DBS in suppressing pathological low-frequency oscillatory neural activity correlated with PD bradykinesia. The model showed that low-

frequency stimulation (<40 Hz) was ineffective in suppressing the PD-related low-frequency oscillatory activity in GPi. PD low-frequency oscillatory power decreased gradually for frequencies between 50 and 130 Hz and saturated at frequencies higher than 150 Hz.

Cortico-Spino-Muscular Interactions

An alternative view to the observed abnormal slowness of movement in PD bradykinesia was

Basal Ganglia: Bradykinesia Models, Fig. 2 Neural architecture of the dopamine modulated cortico-spinal model with muscle spindle feedback to cortex. Top: basal ganglia module (GO signal representing the opening of the thalamocortical gate via inhibition of GPi response). Middle: cortical module for trajectory formation. Bottom: opponent-processing spino-muscular module for agonist-antagonist-agonist muscle activation. Arrow black lines, excitatory projections; solid dot black lines, inhibitory projections; diamond-dotted green lines, dopamine modulation; solid arrow gray lines, excitatory feedback pathways

from muscle spindles. Solid dot gray lines: inhibitory feedback pathways from muscle spindles. GO, globus pallidus internal segment (GPi) output signal; P, bidirectional co-contractive signal; T, target position command; V, difference vector (DV) activity; u, desired velocity vector (DVV) activity; A, current perceived position vector (PPV) activity; M, alpha motoneuronal activity; R, Renshaw cell activity; X, spinal type-b inhibitory interneuronal activity; I, spinal type-a inhibitory interneuronal activity; S, static γ MN activity; D, dynamic γ MN activity; i and j, antagonist cell pair

proposed by Cutsuridis (Cutsuridis 2006a, b, 2007, 2010, 2013; Cutsuridis and Perantonis 2006). He suggested that the observed abnormal slowness of movement in PD bradykinesia is due to inadequately activated motor cortical and spinal cord centers because of not only dopamine reduction in basal ganglia but also in cortical and spinal sites. His models, which were population-based models, were composed of two modules coupled together: (1) the cortical module and (2) the spino-muscular module (see Fig. 2). Both modules and their corresponding neuronal components were modulated by dopamine. The cortical module computed the motor commands sent to the spino-muscular module. The spino-muscular module was an opponent-processing control model of how spinal circuits afford independent voluntary control of joint stiffness and position. Both modules consisted of all major neuronal populations as they have been reported in the experimental literature. The model accounted for all physiological and behavioral phenomena as they have been described in a previous section. Model simulations showed that reduction of DA in cortical and subcortical motor areas disrupts, via several pathways, the rate of development and peak neuronal activity of primary motor cortical cells. These changes lead in delays in recruiting the appropriate level of muscle force sufficiently fast and in a reduction of the peak muscle force required to complete the movement. Repetitive and sometimes co-contractive patterns of muscle activation are needed to complete the movement. These disruptions result in an abnormal slowness of movement.

In a subsequent study, Cutsuridis (2011) investigated the origins of the co-contractive and repetitive pattern of muscle activation as observed in PD bradykinesia. Computer simulations showed that an oscillatory disrupted GPi response signal comprising at least two excitation-inhibition sequences as an input to a normally functioning cortico-spinal model of movement generation resulted in a repetitive but not co-contractive agonist-antagonist pattern of muscle activation. A repetitive and co-contractive pattern of muscle activation resulted when also dopamine was depleted in the cortex. Additional dopamine depletion in the spinal cord sites resulted in a

reduction of the size, duration, and rate of change of the repetitive and co-contractive EMG bursts. These results had important consequences in the development of dopamine replacement therapies in cortex and spinal cord, which could alleviate some of the impairments of PD such as slowness of movement (bradykinesia).

Basal Ganglia: Control of Saccades

Benoît Girard

UMR 7222, ISIR, Sorbonne Université, CNRS, Paris, France

Definition

The basal ganglia are a set of subcortical interconnected nuclei, subdivided in parallel circuits. They form loops with specific cortical and subcortical regions and play a central role in the selection of actions as well as in learning to bias these selections towards the most profitable options. One of these loops appears to be specialized in saccadic eye movements. Most of the existing computational models consider that it is responsible for the choice, among all possible targets, of the target of the next saccade.

Detailed Description

Basal Ganglia Saccadic Circuitry

The basal ganglia are a set of subcortical nuclei common to all vertebrates (see ► [“Basal Ganglia: Overview”](#)). The basal ganglia are components of two main types of loops: cortico-baso-thalamo-cortical loops (Alexander et al. 1986) as well as subcortical ones (McHaffie et al. 2005). Within these two categories, sub-loops can be characterized, dedicated to various functions; one cortical loop dedicated to eye movements has been identified, as well as a few subcortical ones, all projecting to the superior colliculus, where

information converges to allow the generation of eye movements (see ► [“Oculomotor Control, Models of”](#)). The cortical loop receives contributions from the frontal eye fields, the supplementary eye fields, the dorsolateral prefrontal cortex, and the parietal cortex and goes through the ventral anterior, ventrolateral, and medial dorsal thalamic nuclei. The subcortical ones all receive inputs from the superior colliculus via the lateral posterior, the intralaminar, and the pulvinar nuclei of the thalamus.

The outputs of the basal ganglia are inhibitory and tonically active, so that at rest, they maintain their targets under constant inhibition, preventing their activation. The generic role of the basal ganglia is understood as an action selection system, used to solve resource allocation problems (Mink 1996; Redgrave et al. 1999): competing channels within the basal ganglia represent the different potential actions, and when simultaneous inputs activate different channels, the basal ganglia resolve the competition and disinhibit only one of the outputs and thus allow the activation of a single action. In the context of saccadic eye movements, at a given moment, the activities caused by multiple points of interest present in the visual field are susceptible of eliciting multiple saccades, which would allow for the refined analysis by the fovea of these points of interest. The role of the basal ganglia is thus understood as filtering these multiple solicitations in order to keep only the one with the highest priority.

The basal ganglia also interact with dopaminergic nuclei (the ventral tegmental area and the substantia nigra pars compacta): the basal ganglia project to these nuclei and receive modulatory projections at the striatal, pallidal, and subthalamic levels. The current theory proposes that these interactions are the neural substrate of reinforcement learning. They would allow learning, by trial and error, of which actions are the most profitable and would bias the selection process accordingly. The dopaminergic signal is thought to correspond to a measurement of the reward prediction error, which is used to modify the strength of the cortico-striatal synapses according to temporal-difference learning algorithms (see

► [“Reward-Based Learning, Model-Based and Model-Free”](#)). In the saccadic eye movement context, this would be the substrate of the evaluation of the priority of the competing targets, allowing the brain to make the best decision according to experience.

Electrophysiological recording in monkeys showed that saccade-related activity in the basal ganglia of monkey is quite rich (Hikosaka et al. 2000). Input neurons in the striatum exhibit visual and motor saccade-related activity, which is also reflected in the output activity of the substantia nigra. But more interestingly, one third of the neurons have a working memory-specific activity: some of them have visual or motor burst activity only for memory-driven saccades, while the rest have sustained activity while the position of a target is kept in working memory.

Computational Models of the Basal Ganglia Saccadic Circuitry

Relatively few computational models of the basal ganglia have specifically targeted the saccadic circuitry (Dominey and Arbib 1992; Dominey et al. 1995; Brown et al. 2004; Chambers et al. 2005; N’Guyen et al. 2010, 2014; Guthrie et al. 2013; Thurat et al. 2015; Cope et al. 2017; James et al. 2018); thus no final consensus about the role and the specific mechanisms of the basal ganglia saccadic circuit has been reached. All of them have been built at the same level of description, using variations of rate-coding models of neuron populations.

A specificity of models of the saccadic basal ganglia, compared to other basal ganglia models (see ► [“Basal Ganglia: Overview”](#)), is that the targeted motor systems (namely, superior colliculus and brainstem saccade generators) are relatively well known and have already been extensively modeled. Consequently, most of the aforementioned models include motor components allowing to simulate actual behavior.

All of these models consider that the neurons that are involved in saccades towards visible targets belong to a circuit in charge of selecting the target of the next saccadic movement in a winner-

takes-all manner, in line with the current understanding of the general basal ganglia function (see ► [“Basal Ganglia: Mechanisms for Action Selection”](#)). Those models are based on traditional basal ganglia computational models, adapted to saccade selection: each channel in competition codes for a given saccade metric, and the selected channel disinhibits the area of the superior colliculus specifically encoding that metric. The common selection mechanism among those models is based on the focused inhibition of the striatum, by which each channel tries to inhibit its output, and the diffuse excitation of the subthalamic nucleus, used to excite the competitors.

The models which also incorporate reinforcement learning (Dominey et al. 1995; Brown et al. 2004; N’Guyen et al. 2010, 2014; Guthrie et al. 2013) rely on variations of classical temporal-difference reinforcement learning algorithms (see ► [“Reinforcement Learning in Cortical Networks”](#)). In these models, derived from machine learning theories, the dopamine released in the striatum is supposed to correspond to the reward prediction error signal used by these algorithms; it drives the modifications of the strength of the cortico-striatal synapses.

Notably, in the Dominey and Arbib (1992) model, a second loop parallel to the “visual” one is dedicated to working memory. It is supposed to select which of the current potential targets have to be stored, in order to allow for saccades towards targets that may disappear from the visual field. Such a functionality requires a remapping capability: as the frontal eye field, parietal cortex, or superior colliculus maps, which are supposed to store these memories, are retinotopic, the positions of the next saccades have to be updated after each eye movement. This mechanism can be extended to store the order of the targets, allowing for a more elaborated sequence generation capability (Dominey et al. 1995). Note that models of the role of the basal ganglia in working memory have been proposed in other contexts and could easily be adapted to the saccadic function (see ► [“Working Memory, Models of”](#)).

Concerning the subcortical basal ganglia loops through the superior colliculus, no model has ever considered the cohabitation and the possible interactions of the three anatomically described circuits

(McHaffie et al. 2005). Those which considered the basal ganglia-superior colliculus loops included only one of them. Earlier models used it in a slave mode (Brown et al. 2004), where it executes the motor decisions taken by a master cortical loop; more recently it has been considered as an additional player operating in parallel to the cortical loops (Chambers et al. 2005; N’Guyen et al. 2010, 2014; Cope et al. 2017; James et al. 2018), and its possible ability to autonomously make decisions hasn’t been much explored yet (Thurat et al. 2015).

Medicine, New Haven, CT, USA

Definition

The basal ganglia (BG) participate not only in the selection of motor plans but also in perceptual

decision-making. The functional structure of the BG and their close interconnections with the cortex and dopamine system allow the BG to be actively involved in the perceptual decision-making processes.

Detailed Description

The role of the BG in perceptual decision-making processes has recently attracted much attention (Ding and Gold 2013). Although the BG were much earlier proposed to be the central substrate for action selection and habit learning (Graybiel 1995; Mink 1996; Redgrave et al. 2010), their active participation in perceptual decision-making has been investigated only more recently (Ding and Gold 2010). The BG have close interaction with the frontal cortex and the lateral intraparietal area (LIP), where are believed to be the sites of evidence accumulation in decision processes (Gold and Shadlen 2007; Huk and Shadlen 2005; Kim and Shadlen 1999). The BG also have prominent interaction with the downstream subcortical motor-related areas, such as the thalamus and the superior colliculus (SC), and the midbrain dopamine system (Hikosaka et al. 2000). As diagrammed in Fig. 1, information from the cortex can be transmitted to the thalamus and SC through three BG pathways: (1) the direct pathway, from the striatum directly to the output nuclei GPi/SNr; (2) the indirect pathway, from the striatum through the GPe and STN to the output nuclei; and (3) the hyper-direct pathway, from the cortex directly to the STN then to the output nuclei. The opposing effect of dopamine signals on striatum medium spiny neurons that project through the direct and indirect pathways differentially makes the BG suitable for implementing reward dependence learning during the training process in decision-making tasks (Gerfen and Surmeier 2011). In addition, the hyper-direct pathway provides a natural substrate for inhibitory control when an evidence accumulation process needs to be cancelled. Parkinson’s disease (PD), originating from depleted dopamine levels within the BG, shows significant disruption of BG activity (DeLong and Wichmann 2009; Obeso et al. 2008). Impairment in perceptual decision-

alternatives, i.e., the multi-hypothesis sequential probability ratio test (MSPRT) (Baum and Veeravalli 1994). A model used to explore this concept (Bogacz and Gurney 2007) was based on the same BG functional structure as employed in a previous work (Gurney et al. 2001). In this model, each BG nucleus was represented by its average firing rate. The formula for detection probability in MSPRT was first log-transformed, and then each term in the expression for the log-transformed probability was connected with the firing activity of the STN and GP (GPe of primates). This mapping posed requirements for the input–output relation in these two nuclei. Specifically, the STN firing rate was required to be an exponential function of the inputs from the cortex and from the GP, while the GP firing rate was related to the summation of STN output for different channels corresponding to each alternative action. These requirements for the STN and GP input–output relationship were supported by experimental data from *in vitro* measurements of rat BG. The implementation of MSPRT could also be extended to include the indirect pathway. In this model, the interaction between the direct and hyper-direct pathways and the diffusive innervation from the STN to the GP and entopeduncular nucleus (EP), which is the homologue of GPi of primates, are essential for the BG in implementing the MSPRT.

Basal Ganglia Mechanism for Optimal Threshold Modulation

A biophysically based spiking network model involving the BG, the cortex, and the SC has been proposed to provide a mechanism for setting and adjusting the threshold in perceptual decision-making (Lo and Wang 2006). In this model, integrate-and-fire neuron model was used to describe individual neurons and tuned to specific properties in each area. The SC neurons fired a burst when the input was higher than a threshold value. The cortical circuit was modeled as an attractor network in which evidence accumulation occurred (Wang 2002). The cortical circuit projected to the SC through two routes: one was

direct projection from the cortex to the SC and the other route through the BG to the SC. In the BG, only the direct pathway was included. The neurons in the striatum were designed to be silent and fire spikes only when the input was higher than a threshold level. When one of the competing populations in the cortex reached a value that drove the CD neurons to spike, the output nucleus SNr was inhibited, which in turn led to a disinhibition of the SC. When the SC was disinhibited, it could fire a burst in response to the excitatory input arriving directly from the cortex. This burst sent feedback to the cortex, terminated the evidence accumulation there, and set a threshold for perceptual decision-making. The SC burst was turned off by local recurrent connections within the SC. It was found that adjusting the strength of the corticostriatal connection could modulate the threshold within a wide range. On the contrary, adjusting the cortex to SC connection strength could only modestly modulate the threshold. A large range of threshold variability is beneficial when a subject needs to make a transition between response speed and accuracy (Gold and Shadlen 2002). In this model, modulation of the corticostriatal connection led to an inverted u shape of reward rate, reflecting a trade-off between speed and accuracy. The peak reward rate could be shifted according to the task difficulty. Physiologically, the modulation in the corticostriatal connection efficacy could be realized by a reward-dependent reinforcement learning process through dopaminergic synapses observed extensively in the striatum projection neurons (Gerfen and Surmeier 2011). Further experiments are needed to test this hypothesis.

Future Directions

Computational modeling represents an important approach in investigating possible roles of the BG in perceptual decision-making. Such work usually invokes some assumptions that require further experimental testing and also suggests new research directions. For example, in some circuit models, the STN and striatum received the same copy of input from the cortex, which usually

represents evidence accumulated over time (e.g., Bogacz and Gurney 2007). But further experiments are needed to clarify the origin of cortical inputs to the direct and hyper-direct pathways of the BG (Mathai and Smith 2011). Ramping of striatal neuronal activity during evidence accumulation has been observed in primates (Ding and Gold 2013) and will curtail the efficiency of a corticostriatal mechanism for threshold modulation that includes only the direct pathway of the BG (as introduced in Lo and Wang 2006). Therefore, an extension of such a mechanism to incorporate the new experimental observation is called for, and experiments are needed to test the idea that the corticostriatal connection strength is modulated during tasks requiring a speed-accuracy trade-off.

Definition

- Dopaminergic (DA) neurons are defined as neurons synthesizing and containing the neurotransmitter and neurohormone dopamine. Such neurons release dopamine synaptically as well as dendritically (Bustos et al. 2004).
- The electrophysiological signatures of this neuron are broad action potentials (Fig. 1) and a low-frequency, regular spontaneous activity (Fig. 2a).
- A distinctive property of the DA neuron is that it differentially responds to different types of excitatory synaptic inputs (Fig. 2a, b).
- Models have explained these properties and connected them with one another and with particular current compositions (Figs. 3 and 4).

Detailed Description

Importance

The central dopamine system is involved with many behavioral and cognitive tasks (Carlson

Basal Ganglia: Dopaminergic Cell Models, Fig. 1 A single spike of a DA neuron

1999). Dopamine neurotransmission is found to play a role in addictive behavior (Wise 2004) and is altered in psychiatric disorders (Strange 2001). DA neurons fire a burst of action potentials whenever a subject or an animal receives an unpredicted reward or a reward-predicting stimulus (Schultz 2002, but see Redgrave and Gurney 2006). Do the DA neurons synthesize the reward-related signal by some type of neuronal computation, or do they simply relay a signal generated elsewhere? This question motivates the research on the DA neuron and leads to the more specific questions addressed in experiments and modeling.

Anatomy

Midbrain DA neurons are positioned within three cell groups in different brain areas: the ventral tegmental area (VTA), the substantia nigra pars compacta (SNc), and the retrorubral area. There is no clear anatomical distinction between the groups, but heterogeneities in biophysical properties of the DA cells both within and between these groups are documented (see, e.g., Wolfart et al. 2001; Neuhoff et al. 2002; Kotter and Feizelmeier 1998). Nevertheless, the characteristics listed below are common for all three groups of midbrain DA neurons.

Basal Ganglia: Dopaminergic Cell Models, Fig. 2 Firing patterns of DA neurons. **(a)** Low-frequency background firing is replaced by a burst during NMDA receptor activation (e.g., by glutamate iontophoresis). The blockade of the spike-producing fast sodium current (with TTX) reveals subthreshold oscillations. **(b)** Neither applied

depolarization nor activation of the AMPA receptor evokes a burst. **(c)** The blockade of the calcium-dependent potassium current (by apamin) reveals subthreshold plateau potentials. The dashed line shows the spike threshold of -40 mV

Firing Patterns

DA neurons show multiple activity patterns: low-frequency regular (tonic) spiking and different types of bursting. Mechanisms of the firing patterns of the DA neuron are currently debated in the literature. Here, we present most established results and the different views.

Background Firing

In isolation, DA neurons spontaneously display low-frequency (1–5 Hz) tonic spiking. A less regular pattern of a similar average frequency is most commonly seen *in vivo*. Together, these two low-frequency patterns are called background firing.

The major properties of background firing are:

Basal Ganglia: Dopaminergic Cell

Models, Fig. 3 Calcium processes generating the subthreshold oscillations: the persistent L-type calcium current is responsible for depolarization and simultaneous accumulation of intracellular calcium, whereas the SK-type calcium-activated potassium current produces the repolarization phase of the oscillation. These two currents constitute a calcium-potassium mechanism for pacemaking in DA neurons

Basal Ganglia: Dopaminergic Cell

Models, Fig. 4 Generation of the oscillatory plateau potentials that underlie bursting induced by bath application of NMDA relies on the NMDAR current and Na^+ - K^+ exchanger

- Injection of a depolarizing current can increase the frequency of repetitive firing only up to 10 Hz (Fig. 2b; Richards et al. 1997).
- **Modeling** and experiments have shown that, during its background firing, DA neuron is class 1 excitable, which means that its frequency grows continuously from zero as an injected current grows (Lobb et al. 2010; Morozova et al. 2016a).
- Higher firing rates are possible during a transient at the onset of the depolarization.
- **Modeling** suggests that the frequencies remain low due to very weak spike-producing currents:
 - The current initiating the spike is weak: the maximal conductance of the fast sodium current is drastically lower than

in fast-spiking neurons (Kuznetsova et al. 2010).

- The spike-initiating current remains inactivated: the potassium currents causing hyperpolarization after a spike (after hyperpolarizing or AHP currents) are weak and cannot fully remove inactivation (Kuznetsov et al. 2006; Drion et al. 2011), or the inactivation is slow (Qian et al. 2014).

This has two consequences, which contrast the DA neuron with other neuron types:

1. The action potentials generated by these currents are broad (Fig. 1).
2. Background firing must rely on a subthreshold oscillation to be robust.

- Two types of the subthreshold oscillations were found:
 - Calcium-based (Fig. 3; see, e.g., Harris et al. 1989); the corresponding minimal model includes only two currents, L-type calcium and SK-type calcium-activated potassium (Amini et al. 1999; Wilson and Callaway 2000).
 - Sodium-based (calcium-independent; Yung et al. 1991; Nedergaard and Greenfield 1992; Chan et al. 2007; Guzman et al. 2009; Blythe et al. 2009; Khaliq and Bean 2010).
- **Modeling** has shown that the sodium and calcium currents contribute to the same oscillatory mechanism responsible for both spiking and subthreshold oscillations (Puopolo et al. 2007; Drion et al. 2011).
- The calcium-based oscillatory mechanism is distributed along dendrites (Wilson and Callaway 2000), and a special type of synchrony among dendrites and the soma sets in due to electrotonic coupling (Medvedev and Kopell 2001; Medvedev et al. 2003). The frequency of background firing results from a compromise between the oscillations arising in the soma, dendrites, and axon initial segment (AIS; Meza et al. 2018).
- The background frequency in DA neuron subpopulations correlates with the presence of a calcium-binding protein calbindin and the strength of the hyperpolarization-activated cationic current I_h (Neuhoff et al. 2002), and this relation is reproduced in modeling (Evans and Khaliq 2015).
- Both in vivo and in vitro, bursting is dependent on the activation of NMDA receptors (Fig. 2a).
- Activation of AMPA receptors alone does not elicit bursting (Fig. 2b; Chergui et al. 1993; Overton and Clark 1997; Tong et al. 1996; Morikawa et al. 2003; Deister et al. 2009).
- **Modeling** has shown that the failure to burst in response to AMPAR stimulation follows immediately from the limited frequency of the response to applied depolarization (see above and Kuznetsov et al. 2006).

Bursts In Vivo

Firing rates of ≥ 20 Hz can be achieved for irregularly distributed short time intervals in the DA neuron in vivo (Hyland et al. 2002). The main properties of these bursts are:

- The bursts are singular events as opposed to repetitive bursting (but see Freeman et al. 1985).
- Bursts are not superimposed on a depolarizing plateau, and may not be followed by a pause in activity.
- Within the burst, the spike amplitude progressively decreases, and the spike duration and interspike interval progressively increase (but see Hyland et al. 2002).
- Burst evocation relies on excitatory synaptic inputs.
- NMDA but not AMPA receptor activation is critical for the burst (Chergui et al. 1993; Overton and Clark 1997; Tong et al. 1996; Meltzer et al. 1997).
- The frequency of burst occurrence can be regulated differentially from the average firing rate in vivo (Grace and Bunney 1984; Tepper et al. 1995), which was explained in **modeling** (Canavier and Landry 2006).
- The burst is critically dependent on calcium (Grace and Bunney 1984).
- SK channel blockers induce burst firing in vivo (Ji and Shepard 2006; Waroux et al. 2005).
- Blockade of GABA_A receptor currents has been shown to induce bursting in DA neurons, suggesting a disinhibition hypothesis of DA burst firing in vivo (Tepper et al. 1995).
- **Modeling** has shown that synchronizing GABA input to DA neurons may also induce

Burst Firing

The stereotypic response of the DA neuron to an unpredicted reward is a burst of activity with firing frequencies above 20 Hz. Different experiments result in bursts that are significantly different from one another (see, e.g., Johnson and Wu 2004; Overton and Clark 1997). A central question is how similar is in vitro bursting to that observed in vivo. The main features of each type of bursting in the DA cell are described below with the following common properties to be emphasized:

bursting by short pulsatile disinhibitions (Morozova et al. 2016b). The mechanism is different from above because it requires the average GABA-mediated inhibition to stay high and dynamically replace the long-lasting SK-mediated inhibition.

Modeling proposed two distinctly different mechanisms for in vivo bursting:

- In Kuznetsov et al. (2006) and Ha and Kuznetsov (2011, 2013), the NMDAR current directly interacts with the subthreshold oscillatory mechanism and increases the frequency of oscillations (Fig. 2a). This provides the distinction between responses to AMPA and NMDA receptor activation.
- In Komendantov and Canavier (2002) and Canavier and Landry (2006), the role of the NMDAR current is identified as opposing the SK current and therefore reducing the amplitude and duration of the AHP.

In Vitro Bursting Induced by Stimulation of NMDA Receptors

Repetitive bursting can be elicited in DA neurons in vitro via bath application of NMDA (Johnson and Wu 2004). The properties of this bursting are:

- This is a repetitive bursting pattern.
- The high-frequency firing is superimposed on a depolarizing phase of a subthreshold oscillation called a plateau potential.
- This bursting is Ca^{2+} -independent: bursting persists in Ca^{2+} -free solution, or upon chelation of intracellular Ca^{2+} .
- This bursting is critically dependent on extracellular sodium (Johnson et al. 1992).

These properties contrast with those for bursting in vivo (see above).

Other in vitro stimulation techniques evoked bursts more similar to those found in vivo. A burst has been observed after extracellular electrical stimulation (a train of short pulses) or iontophoresis of a glutamate receptor agonist onto the DA cell (Morikawa et al. 2003; Blythe et al. 2009; Deister et al. 2009).

Glutamate influences the firing through NMDA receptors:

- Subsequent bath application of an NMDA receptor antagonist inhibited the burst.
- In dynamic clamp experiments, injection of a virtual NMDA current elicited a burst (Deister et al. 2009; Putzier et al. 2009).
- Removing the voltage dependence of the virtual NMDAR current, which converts it into AMPAR-like current, abolished the burst.

The properties contrasting these bursts from bursts elicited by other methods in vitro, and resembling bursts in vivo, are:

- Spikes within a burst are not superimposed on a depolarizing plateau.
- The hyperpolarization after the burst originates from a separate pathway, which can be blocked or desensitized without affecting the burst.
- Switches between the low-frequency background firing and the high-frequency bursts follow the on-off pattern of the stimulation.

Thus, the high-frequency firing cannot be a consequence of the depolarizing phase of the underlying plateau potentials.

Modeling has shown that the high-frequency firing can be elicited independently of the plateau potentials (Kuznetsov et al. 2006). However, the plateau potentials and the high-frequency firing share certain properties:

- The nonlinear voltage dependence of the NMDAR current is critical for evoking plateau potentials (Li et al. 1996; Canavier 1999; Komendantov et al. 2004), as well as for the high-frequency oscillations (Kuznetsov et al. 2006; Ha and Kuznetsov 2013).
- By contrast, activation of linear currents, such as AMPAR or GABAR, suppresses plateau potentials as well as the high-frequency firing.

In Vitro Bursting Induced by Apamin

Repetitive bursting of the DA neuron was observed during the bath application of an SK current blocker apamin (Fig. 2c; Shepard and

Basal Ganglia: Dopaminergic Cell Models, Table 1 Comparison of different ways to induce a burst in the DA neuron

Property/burst type	In vivo	In vitro			
		NMDA iontophoresis	Bath NMDA	SK block	Bath NMDA + SK block
Repetitive pattern	No	No	Yes	Yes	Yes
Plateau potentials	No	No	Yes	Yes	Yes
Ca ²⁺ dependence	Yes	Yes	No	Yes	No
Na ⁺ dependence	No	No	Yes	No	Yes

Bunney 1991). The main properties of this bursting pattern are:

- This is also a repetitive bursting pattern.
- The high-frequency firing is superimposed on depolarizing plateau potentials.
- Blockade of spike generation preserves the oscillatory plateau potentials underlying bursts (Fig. 2c; Ping and Shepard 1996).
- **Modeling** reproduces the transition from the low-frequency subthreshold oscillation to the plateau potential oscillation upon simulated blockade of the SK current (Amini et al. 1999; Canavier et al. 2007; Oster and Gutkin 2011).
- Without the SK current, DA cells become prone to depolarization block, and each burst collapses to a plateau (Fig. 2c).
- Apamin-induced bursting is critically dependent on calcium: L-type Ca²⁺ channel blocker abolishes the plateau potential oscillations, and this bursting is abolished in Ca²⁺-free medium.
- **Modeling** and modeling-driven experiments show that the ether-a-go-go-related gene (ERG) current contributes to the repolarization phase of the plateau potential wave (Canavier et al. 2007; Ji et al. 2012).
- **Modeling** suggests that the ERG current also provides repolarization after each spike and, therefore, is involved in generation of low- and high-frequency firing (Ha and Kuznetsov 2013).

Together, these characteristics suggest that this bursting pattern is different from in vivo bursting (see above).

Bursting has been shown to be most robust in simultaneous bath application of NMDA and

apamin. Properties of bursting in this case are similar to those for whole bath NMDA-induced burst firing (see above) (Johnson and Wu 2004). This suggests that apamin, by blocking the SK current, can facilitate two different bursting mechanisms, one of which is intrinsic and the other based on the NMDA receptor activation. **Modeling** reproduced the facilitation of high-frequency firing during simulated NMDAR activation combined with partial blockade of the SK current (Oster and Gutkin 2011) (Table 1).

Summary of Models

All models of DA neurons have a conductance-based form

$$c_m \frac{dv}{dt} = \sum_j I_j$$

where v is voltage and I_j are various transmembrane currents. The following firing patterns were reproduced by the inclusion of different currents in various models:

- *Subthreshold calcium-driven oscillations*

A calcium and a calcium-dependent potassium current constitute a mechanism for subthreshold oscillations (Figs. 2a and 3). The calcium current has the form $I_{Ca} = \bar{g}_{Ca} c_{inf}^4(v)(E_{Ca} - v)$, which assumes instantaneous gating. The calibration of the gating function $c_{inf}(v)$ reflects an activation threshold of an L-type current, which is significantly lower in DA cells than in other neurons (~ -50 mV). The calcium-dependent potassium current (SK type) has the form $I_{KCa} =$

$\bar{g}_{KCa} \frac{[Ca^{2+}]^4}{[Ca^{2+}]^4 + k^4} (E_K - v)$, which also assumes instantaneous gating.

- *Spike generation*

The delayed rectifier potassium current is taken in a standard form $I_{DR} = \bar{g}_{DR} n^4 (E_K - v)$. Here, n is a gating variable, which obeys a standard equation $dn/dt = (n_{inf}(v) - n)/\tau_n(v)$. The gating function $n_{inf}(v)$ and time constant $\tau_n(v)$ in this equation are calibrated to reflect high half-activation and slower activation kinetics of the current. This calibration and the current's low maximal conductance weaken the hyperpolarization produced by the delayed rectifier and lead to a low safety factor or robustness of spike generation.

The fast sodium current also takes a standard form with instantaneous activation $I_{Na} = \bar{g}_{Na} m_{inf}^3(v) h (E_{Na} - v)$, where the function $m_{inf}(v)$ reflects the spike threshold of -40 mV. The maximum conductance of this current is quite low, around 550 uS/cm², which gives a moderate slope of the spike upstroke and broad action potentials (Fig. 1).

- *Subthreshold plateau potentials*

Slow subthreshold oscillations called plateau potentials are observed after the blockade of the spike-producing sodium current in two conditions:

- The blockade of the calcium-dependent potassium current (Fig. 2c)
- The activation of a synaptic NMDA receptor current by bath application of an NMDAR agonist

In the latter case (Fig. 4), voltage rises due to the NMDAR current, and the subsequent voltage decline is due to a sodium pump current (Na^+K^+ exchanger): $I_{NP} = \bar{I}_{NP} / (1 + (K_{mNa}/[Na]_i)^{1.5})$, where $[Na]_i$ is the intracellular sodium concentration.

During the blockade of the calcium-dependent potassium current, the subthreshold depolarization is produced by the calcium current. Two mechanisms were proposed for the repolarization phase: the calcium pump current $I_{CP} = \bar{I}_{CP} / (1 + K_{mCa}/[Ca]_i)$ and the ether-a-

go-go-related gene (ERG) current $I_{ERG} = \bar{g}_{ERG} e (E_K - v)$, where e is its activation variable.

- *Responses to synaptic inputs*

An NMDA receptor current elicits high-frequency firing in the DA neuron. The non-linear voltage dependence of the current is assumed to be instantaneous: $I_{NMDA} = \frac{\bar{g}_{NMDA}}{1 + 0.1[Mg]e^{-m_e v}} (E_{NMDA} - v)$, where $[Mg]$ is the magnesium concentration. The low slope of the voltage dependence ($m_e = 0.062$) is critical for the increase of the frequency of spikes or subthreshold oscillations during NMDA application.

An AMPA receptor current differs by its linearity: $I_{AMPA} = \bar{g}_{AMPA} (E_{AMPA} - v)$. Constant (tonic) AMPAR current does not elicit high-frequency firing.

Complete description of these models can be found in the literature cited above.

Conclusions and Future Directions

Our understanding of the electrophysiological properties of the DA neuron and the underlying mechanisms is not complete. However, modeling studies have clarified some relations between its characteristics.

Weak Spike-Producing Currents Determine Low-Frequency and Broad Action Potentials

First, the high-frequency firing within bursts must be considered in the context of limited firing frequencies in response to applied depolarization (but see Blythe et al. 2009). The high frequency is not a simple consequence of a depolarizing plateau potential. The spike-producing currents cannot reliably support repetitive firing, and both high- and low-frequency firing must rely on the subthreshold oscillations to be robust. The main reason is that the fast AHP currents are weak, as suggested by modeling studies. Additionally, the fast sodium current has a drastically lower maximal conductance compared to that in fast-spiking neurons. This results in even weaker activation of

the fast AHP currents and simultaneously ensures the broad action potentials, which are characteristic for DA neurons.

Calcium-Dependent and Calcium-Independent Oscillations

Modeling suggests that a single oscillatory mechanism combines multiple currents that support subthreshold oscillations in different experimental conditions. Both calcium and subthreshold sodium currents contribute to the depolarizing phase of the oscillation. Similarly, both calcium-dependent and voltage-dependent currents must contribute to the repolarization phase of the oscillation. The SK current is known to provide the calcium-dependent component. The ERG current is suggested by modeling studies as the voltage-dependent component.

Distinct Responses to AMPA and NMDA Receptor Stimulation

The delicate oscillatory mechanism of the DA neuron results in its distinct responses to different stimuli. In general, a passive (linear) or injected (constant) current can only impair oscillations. To complement the oscillatory mechanism, the current must be active (nonlinear). This is the difference between AMPAR and NMDAR currents: the NMDAR current contributes to the regenerative depolarization phase of the oscillation. In various other types of neurons, the spike-producing oscillatory mechanism is so powerful that the type of stimulation does not make much difference. Taken together, because the oscillations in the DA neuron are much less robust than in fast-spiking neurons, the ability of an input to contribute to the oscillation becomes critical, and the difference between NMDA and AMPA receptor currents is revealed.

Major Future Directions for Modeling Firing Patterns of the DA Neuron

- Combine mechanisms for all types of oscillations in a single model to examine their interaction and establish the connections among different experiments.
- Model burst evocation in realistic in vivo-like conditions, which includes accurate calibration

of the glutamate and GABA synaptic inputs and dynamic gating of receptors.

- Study the influence of dopamine autoreceptors on firing of the DA neuron.
- Investigate the functional consequences of the distinctive morphology of the DA neuron, such as the separation of each spike into somatodendritic (SD) and initial segment (IS) components due to the distant location of the axon hillock from the soma.

Basal Ganglia: Globus Pallidus Cellular Models

Dieter Jaeger

Department of Biology, Emory University,
Atlanta, GA, USA

Definition

The globus pallidus is a part of the basal ganglia in the vertebrate brain. Cellular models of the globus pallidus are computer representations of the specific dynamics of globus pallidus neurons.

Detailed Description

Goals of Globus Pallidus Cellular Models

Detailed cellular models of globus pallidus (GP) neurons are typically constructed to better understand how they integrate synaptic input and how their intrinsic properties contribute to the input-output function of the GP. The exploration of GP function in larger network models is typically carried out using less detailed cell models. The level of complexity and biological realism best used for a GP neuron model depends on the questions one wants to address (Herz et al. 2006) and ranges from simple integrate-and-fire models to complex full morphological reconstructions with a full complement of ion channel types found in these neurons.

Models that Capture the Detailed Dynamic Properties of Globus Pallidus Neurons

The GP is divided into an external (GPe) and internal (GPi) segment. All detailed models to date have focused on GPe properties. The GPe is primarily made of large GABAergic inhibitory projection neurons with very few interneurons. Anatomically GPe neurons can be subdivided into arky pallidal neurons projecting almost exclusively to the striatum and prototypic neurons, which project to multiple downstream targets like the GPi and STN (Mallet et al. 2012). The electrical properties of GPe neurons are overlapping (Deister et al. 2013) and can be simulated by a variable density of the different ion channel types in the membrane (Gunay et al. 2008). Biophysically detailed GPe neuron modeling has revealed a complex dependency of cellular dynamics on the interactions between multiple voltage-gated channel types. The hallmark of these neurons is a fast spontaneous regular spiking activity that depends on steady depolarization through a persistent sodium channel (Mercer et al. 2007), though arky pallidal neurons have less persistent sodium current and slower spontaneous spike rates (Abdi et al. 2015). Each spike causes a calcium inflow through voltage-gated calcium channels and subsequent activation of calcium-dependent small conductance (SK) potassium channels that results in a spike – afterhyperpolarization that regularizes spiking (Deister et al. 2009). A biophysically detailed modeling study showed that dendritic integration of synaptic input in GPe neurons may depend on dendritic fast sodium channels that can lead to synaptically evoked dendritic spike initiation (Edgerton et al. 2010). Further, the phase response curve (i.e., the spike time delay or advance resulting from synaptic input) was shown to be principally different for distal dendritic input (Schultheiss et al. 2010), where excitatory input at the beginning of a spike cycle can lead to a delay in subsequent spiking (type II phase response curve). Overall, it is the detailed examination of local dendritic processing that provides the most compelling rationale for detailed morphological neuron models, and the GPe neuron models are no exception in revealing potentially significant aspects of such dendritic processing. Biophysically detailed

GPe models are available for download in the Yale ModelDB archive at <http://senselab.med.yale.edu/modeldb/ModelList.asp?id=88217>.

Models that Capture the Interaction Between GP and Subthalamic Nucleus (STN)

A special GPe neuron modeling interest in the first decade of the twenty-first century has been concerned with the interactions between STN and GPe in the generation of pathological rhythmic bursting activity that is observed in Parkinson's disease. The feedback pathway consisting of STN excitation of GPe and GPe inhibition of STN has been suspected to be the cause of such pathological oscillations based on earlier experimental results in slice cultures (Plenz and Kitai 1999) and was first modeled with a set of connected STN and GPe single-compartment neurons by the group of David Terman at Ohio State University (Terman et al. 2002). This model set off a host of subsequent modeling studies confirming the possibility of triggering oscillations in this network, notably in the beta band, with synaptic changes and disrupted striatal input patterns to GPe expected in parkinsonism (Holgado et al. 2010; Park and Rubchinsky 2012). These models typically employ dynamical systems analysis to examine the parameter range and stability required to exhibit different activity patterns. Nevertheless, to date the question of where beta activity originates in Parkinson's disease is not solved, and cortical and striatal mechanisms are also thought to be important contributors (McCarthy et al. 2011; Kerr et al. 2013) and may interact with GP-STN oscillations (Nevado-Holgado et al. 2013; Ahn et al. 2016). Several models of GP-STN interactions are available for download in the Yale ModelDB archive.

Integration of GP Neuron Models in Large-Scale Network Simulations of Action Selection

The ultimate question of GP neuron modeling of course concerns the computational function of GP in basal ganglia information processing. Notably, GP neurons are included in basal ganglia network models that perform an action selection function (Gurney et al. 2001a, b; Humphries et al. 2006; Bogacz and Gurney 2007; Bogacz et al. 2016). This network simulation paradigm gives GPi a

function as the key output of the selection pathway where selected actions are represented by decreased activity. In contrast GPe is part of a control pathway that allows setting selection thresholds via global modulation of GPi output rates. Networks are typically modeled with populations of leaky integrate-and-fire neurons with synaptic time constants matched to experimental data. In this type of model, simulated GP spike trains can replicate key features of rodent recordings (Magill et al. 2001). The Humphries et al. (2006) spiking network model is available on the Yale ModelDB archive.

Modeling the Effects of Deep Brain Stimulation in Parkinson's Disease

Deep brain stimulation (DBS) in STN or GP has proven to be an effective treatment for Parkinson's disease in many patients (Dostrovsky et al. 2002; Vitek et al. 2012). The mechanisms underlying these beneficial effects have been examined with simulations including GP neuron models at all levels of abstraction ranging from detailed biophysical dendritic models to network function. Detailed dendritic GP neuron models have been used to establish how pallidal deep brain stimulation results in changes of local neuron depolarization and firing (Johnson and McIntyre 2008). The effect of DBS to suppress pathological rhythmic synchronization has been the subject of numerous simulation studies and is typically carried out in networks of single-compartment neurons including GP as one structure (Rubin and Terman 2004; Cleary et al. 2013; Kang and Lowery 2013). Network modeling has also addressed the question of how stimulation of fibers and neurons in DBS differentially contributes to information flow in cortico-thalamic loops of information processing (So et al).

Basal Ganglia: Habit Formation

Barbara Knowlton

Department of Psychology, UCLA, Los Angeles, CA, USA

Definition

In large part, learning is characterized by the formation of new associations. Habit learning appears to be a form of associative learning that can occur in the absence of awareness of what has been learned. Behaviors that lead to a reward can become habitual with sufficient training. When behaviors are habitual, they can be automatically elicited by antecedent stimuli even when the outcome of the behavior is no longer attractive.

Detailed Description

The Representation of Habits

Fundamentally, habits are associations between stimuli and responses, or S-R associations (Graybiel 2008; Mishkin and Petrie 1984; Packard and Knowlton 2002). For example,

when you are confronted with an intersection on your drive to work, this visual stimulus may automatically elicit a left-turn response after years of driving the same route. S-R associations contrast with arbitrary associations between stimuli that we typically think of as declarative learning, such as learning associations between word pairs. However, the distinction between stimulus-stimulus (S-S) associations and S-R associations does not fall neatly in the distinction between declarative and nondeclarative memory. For example, Pavlovian conditioning is the S-S association of a conditional stimulus with an unconditional stimulus, and at least simple Pavlovian conditioning can occur in the absence of awareness of what has been learned and independently of medial temporal lobe structures, including the hippocampus, that support declarative memory. Thus, both S-S and S-R associations can be formed implicitly.

Properties of Habits

Independence of Awareness

In order to make the case that habit learning is distinct from other types of learning, it is necessary to develop a list of its properties. As stated above, learning of S-R habits does not appear to require awareness of what has been learned. That is, people may be acquiring a habit, and not recognize it until they recognize themselves performing it. A powerful means to examine whether learning depends on awareness is to test amnesic patients. These patients have a selective deficit in declarative memory due to damage in the medial temporal lobe or associated diencephalic structures (Squire and Zola-Morgan 1991). Thus, if these patients are able to learn habits, it would suggest that habit learning can proceed independently of awareness. Several studies have demonstrated that patients with severe memory problems can acquire associations between stimuli and responses normally. For example, in a “weather prediction” task in which different cues were associated with the outcome either “rain” or “sun,” amnesic patients were able to learn to select the correct choice at the same rate as healthy control

subjects. Over about 100 trials, both groups were able to achieve a level of performance significantly above chance. However, amnesic patients were unable to remember much about the testing event, such as the layout of the screen or the order of events on each trial (Knowlton et al. 1996). Amnesic patients’ knowledge of the association between the cues and the outcomes also seems to differ from that of the control subjects. Control subjects were able to answer questions about the cue-outcome associations when posed in a different way than what was present during learning. For example, subjects may be asked to imagine that the outcome is sunny and that two cues had been presented, and they should decide which cues would they most likely be. While control subjects seem to have flexible knowledge of these associations, amnesic patients do not (Reber et al. 1996). It seems that their knowledge of the association between the cues and outcomes is encapsulated as a set of stimulus–response habits, while control subjects have gained declarative knowledge of these associations. While the control subjects may have an S-R representation of the cues and the correct responses that are associated with them, they also appear to have declarative knowledge of which cues are associated with each outcome that allows them flexible access to this knowledge. It appears that the amnesic patients are only able to solve the task using S-R habits, such that the cues come to elicit the correct response (pressing either the sun or rain key). These habits may exist independently of awareness and are only observable when the subject is confronted with the eliciting stimulus.

Lack of Flexibility

Another characteristic of habits is that the knowledge gained is not readily applied in other contexts, for example, in a forced-choice task, in which subjects were presented with a series of pairs of items and were required to make a choice between the items of the pair. One item of the pair was consistently rewarded. Patients with dense amnesia were able to gradually learn to select the correct item across many trials. However, they did not have any explicit knowledge of why they were

selecting one item over the other, and they attributed their choices to preference rather than their experience on previous trials (Bayley et al. 2005). In contrast, control subjects learned to pick the correct item in each pair more quickly, and they were well aware that their choices were based on which item had been rewarded on previous trials. Their conscious memory for the rewarded items of each pair enabled them to pick these items out from among all the items – that is, their memory was flexible in that they could readily demonstrate their memory in a context that was different than the one that was present during training. Although the amnesic patients eventually reached the same level as the control subjects in the original forced-choice task, they were making their responses based on S-R habit. They did not have awareness of which items were rewarded and they were unable to use their knowledge flexibly. This lack of awareness and flexibility of knowledge can be considered hallmarks of habit learning.

Insensitivity to Devaluation

One difficulty in determining whether performance on a task is based on habit or declarative memory is that just about every circumstance in which performance could be supported by a habit, performance also could be supported by declarative memory. If a rat learns to press a lever resulting in a food reward, it may be that it has developed an S-R habit, with the lever automatically eliciting a response. However, it may be that the rat remembers that food appears as an outcome of the lever pressing action, an A-O association. Similarly, a person may open their refrigerator door in order to get food that is known to be inside (and A-O association), or they may be simply opening the door out of “force of habit,” in an S-R fashion.

In order to determine the nature of the memory supporting behavior, we need to use probe tasks. For example, we can test subjects’ awareness and flexibility of knowledge to demonstrate that what was learned differed for control subjects and amnesic patients. However, these tasks did not probe the structure of the underlying association – whether performance was supported by S-R or

A-O connections. In studies of animal learning, this has been accomplished by assessing the effect of devaluing the outcome on subsequent performance. The logic here is that in an S-R association, unlike in an A-O association, the outcome is not represented. Thus, performance of the habit should not change if the outcome is no longer desired (Dickinson 1985). For example, if you are in the habit of turning left at a certain intersection on your route to work, you may unintentionally make this turn one Saturday when you meant to go somewhere else. Although the outcome (getting to work) was not desired at that time, the habitual response persisted when the intersection was encountered. Another example may be entering a room and reaching to turn on a light switch through force of habit. Even when you have learned that the light has burned out or perhaps it is daytime and you do not need any light, the habit persists.

In several studies of instrumental learning, the training schedule was shown to be an important factor as to whether learning is based on an A-O or S-R association (Dickinson et al. 1983; Yin et al. 2004). When rats were trained to press a bar for food under a ratio schedule, devaluing the food reinforcer resulted in a decrease in response rate, suggesting that the rats were pressing the bar in order to get food. In a ratio schedule, reinforcement is given each time the animal makes a certain number of responses – in other words, food is given after every third bar press. In contrast, training rats under an interval schedule leads to performance that is insensitive to reinforcer devaluation. In an interval schedule, reinforcement is given if a response is made at any time during an interval (e.g., 30 s). No more reinforcement is given if 1 or 100 responses are made during the interval. A real-world example may be like checking your mail. After training rats in an interval schedule, one can then make the food that was used during training unattractive to the rats. One way to accomplish this is to give the rats an unlimited amount of the food while they are in their home cage. When they become sated on the food, they are immediately tested to see whether they will continue to respond as vigorously as a hungry rat.

When rats are trained on an interval schedule, devaluation of the reinforcer has no effect. This is some of the strongest evidence that performance can be supported by S-R associations and that such habit learning is distinct from learning the association between responses and their outcomes.

One reason why training with ratio and interval schedules leads to such different underlying associative representations is that the contingency between the response and the outcome differs. Under a ratio schedule, each sequence of responses is reinforced – if responding decreases, the number of reinforcers decreases. However, with an interval schedule, the number of reinforcers received is not nearly so tied to the response rate – under a 30-s schedule – and responding once per second and once per 30 s would yield the same amount of reward. The level of contingency between an action and its outcome appears to be a key factor in whether learning results in a habit (Balleine and Dickinson 1998).

Historically, the idea that learning is based on the formation of stimulus–response habits has been influential. Hull promoted the idea that all learning could be reduced to a series of S-R habits (Hull 1943). The role of reinforcement was to strengthen these S-R bonds. However, this view was challenged by the fact that some types of learning did not seem to be consistent with the acquisition of an S-R habit. The most striking example is latent learning described by Tolman and Honzik (1930), who showed that animals learn the spatial layout of an environment even when not given reinforcement. Although it seems clear in hindsight that not all learning is habit learning, the later acknowledgment that there are multiple learning and memory systems made it clear that habit learning can coexist with other forms of learning. Mishkin and colleagues made this point in drawing the distinction between habit and cognitive learning, with these two different types of learning depending on different brain systems (Mishkin et al. 1984). Differences in the neural architecture supporting these different types of learning give rise to differences in their psychological properties.

Automaticity

Another feature of habit learning that seems to distinguish it from declarative or “cognitive” learning is that it occurs relatively automatically. Declarative learning and the retrieval of information from declarative memory are fairly attention demanding. Memory encoding is poorer when performing a concurrent task, and while retrieval from memory may be accurate under dual task conditions, it is significantly slower (Craik et al. 1996). We certainly understand that being distracted while studying will hamper learning of new facts and that it is more difficult to remember information on a test when a distraction is present. In contrast, habit learning does not seem to benefit as much from focused attention. In fact, it is often when we are distracted that we produce a habitual response when we intended otherwise, such as when we make the turn to go to work when we in fact had set out for a different destination.

The presence of distraction during learning may result in a reliance on the habit learning system under circumstances in which one is likely to form declarative memory representations when attention is not divided. In a study using the probabilistic classification task, subjects learned two different sets of associations (Foerde et al. 2006). They were told that they would be learning to predict the weather in two different cities (Budapest and Prague) using two different sets of cues. The two different sets of cues were in different colors to make it clear which task they were performing on each trial. The subjects predicted the weather for one city under single task conditions – the weather prediction task was the focus of their attention. In other blocks, subjects predicted the weather for the other city while they concurrently performed another task in which they had to keep a running count of the number of tones that were presented. Although subjects performed numerically worse at predicting the weather when they were learning under dual task conditions, performance was similar for the two cities when subjects were later tested under single task conditions for both tasks. This suggests that while the performance on a concurrent task may slightly impair performance of a habit (perhaps by occasionally causing the subject to misperceive

the cues or make the wrong response), it does not seem to impair the acquisition of the habit.

One of the most interesting behavioral findings of this study was the fact that the representations underlying single and dual task learning in these two tasks appeared to be different. For the city in which the task learned under single task conditions, subjects had flexible knowledge of the cue-outcome associations. They were able to accurately assess which cues were most likely to be present if it was rainy or sunny, so they were able to access their knowledge of the cue-outcome associations in a way that was different than that posed in the original task. For the city in which the weather prediction learning occurred under dual task conditions, this flexible knowledge was much less apparent, even though performance on the task itself was fairly normal. These results are consistent with the idea that habit learning can proceed under conditions in which attentional resources are limited. In addition, these data suggest that learning while distracted can result in the learned knowledge restricted to S-R habits rather than flexible declarative representations.

Incremental Learning

An important characteristic of declarative learning is that it can occur in a single trial. We have conscious memories for specific moments in time that we will keep in our entire lives. The unique structure of the hippocampus is thought to be able to support the rapid learning necessary for the encoding of episodes (Rolls 2007). Our experience of habit learning is different in that we think of habits as behaviors that develop over time. Habits are acquired gradually, with feedback incrementally strengthening the bond between stimulus and response (Packard and Knowlton 2002). The neural structures that support habit learning may not be capable of single-trial learning. It may be that the slow incremental learning of habits and the rapid learning of episodes are complementary, ensuring that behaviors that have a long history of reward are automatic and stable while still maintaining the flexibility to alter behavior when there is a conditional change (Squire 1992).

The gradual nature of habit learning is exemplified by the fact that overtraining typically results in goal-directed actions becoming habits. As discussed above, when rats are trained to make an instrumental response under a ratio schedule, performance is goal directed, in that responding will decrease when the reinforcer used is devalued. However, when training is continued, performance will eventually become insensitive to reinforcer devaluation, indicating that the response has become “habitized” (Dickinson 1985). Overtraining may serve to break down the contingency between responding and the outcome, because very few responses are withheld at this point. The animal no longer experiences the consequences of not making a response, so the link between the response and the outcome is less apparent (Dickinson et al. 1983).

The effect of overtraining on the development of habit learning can also be seen using the cross-maze task (Tolman et al. 1946). In this task, a rat is trained to go to a baited arm that is either to the left or to the right of the start arm (e.g., for a rat that starts in the “south” arm, the food reward will always be at the end of the “east” arm). If rats are given a moderate amount of training and are then tested using the opposite start arm (in the example, the “north” arm), they go to the location where they received the reward. However, with overtraining, rats persist in making the same motor response as during training – they turn in the same direction, and thus when they are started from the “north” arm, they turn right and end up in the “west” arm (Hicks 1964; Packard and McGaugh 1996; Fig. 1). Overtraining results in this shift to a reliance on a response strategy, in which the maze elicits a motor response in an S-R fashion.

Dependence on Feedback

Finally, an important characteristic of habit learning is that rewarding feedback is necessary to strengthen the habit. Declarative learning is thought to occur continually and incidentally (Stark and Okado 2003). As in the case of the latent learning procedure described above, information is stored in memory even without

Basal Ganglia: Habit Formation, Fig. 1 The cross maze used to probe whether a rat is responding based on memory for the location of a reward or based on a habitual motor response. If the rat chooses based on its memory for the location of the reward, during the probe test, it will go

to the “place” the reward had been presented (the right arm). If the rat is responding based on habit (making the right-turn “response” when in the maze), it will go to the left arm in the probe trial

reinforcement. For habit learning, reinforcement is thought to be critical for strengthening S-R bonds, even though the reinforcer is not part of the learned representation. One study that specifically examined the role of feedback in habit learning used the probabilistic classification task (Shohamy et al. 2004). In the version of the task used by these investigators, subjects learned to guess which flavor of ice cream (chocolate or vanilla) was preferred by a Mr. Potatohead figure that was presented on each trial. Unbeknownst to the subject, the features that could be present or absent on the Mr. Potatohead were probabilistically associated with either a chocolate or a vanilla preference. The procedure was similar to that used in the weather prediction version of the task for some of the subjects. These subjects made a response (pressing either the “chocolate” or “vanilla” key) and received feedback that they were correct or incorrect on every trial. The other subjects received an “observational” version of the task in which the figures were presented followed by the correct answer (chocolate or vanilla). In the observational task, the same information about the association between cues and outcomes was present, but the subjects did not make a response that was rewarded. It appeared that these two learning situations differ, in that only feedback learning was impaired in patients with Parkinson’s disease. This finding suggests that feedback-based learning is supported by

different neural substrates than observational learning.

The idea that feedback-based and observational learning differ in terms of neural mechanisms is also supported by findings from neuroimaging. Results from a study using the weather prediction version of the probabilistic classification task have shown that when the task is learned with feedback, learning is associated with activation in the striatum, while learning through observation results in activation of medial temporal lobe (Poldrack et al. 2001).

Brain Mechanisms of Habit

Mishkin and Petrie (1984) argue that “Hullian” habit learning and cognitive learning described by Tolman coexist based on the idea that distinct brain systems support different forms of learning. Mishkin and Petrie identify the basal ganglia and medial temporal lobe structures as supporting habit versus cognitive learning. A great deal of support for this idea has come from lesion studies that illustrate double dissociations between the effects of damage to the striatum of the basal ganglia on habits and lesions of the medial temporal lobe on cognitive learning. In nonhuman primates, damage to medial temporal lobe structures including the hippocampus and surrounding temporal lobe cortices results in significant impairment in cognitive memory tasks such as the delayed non-match to sample task (Murray

2000). In this task, the subjects are presented with a sample item and after a delay (from seconds to hours) are presented with the sample item and a different item. The subject's task is to pick the new item. This task requires the monkey to remember an event – the presentation of the sample stimulus – in order to make the correct choice. Learning in this task is unaffected by lesions of the tail of the caudate nucleus – the region which receives visual information from cortex. In contrast these lesions severely impair performance on a concurrent discrimination task (Fernandez-Ruiz et al. 2001). As described above, in this task the subject is given pairs of objects, with one element of the pair consistently rewarded. As discussed previously, this task can also be learned either declaratively or as a set of S-R habits. It appears that when monkeys are given a single trial per day for each discrimination, learning becomes habitual, perhaps because they are unable to readily recall previous trials with such a long delay between them. Under these conditions, lesions of the tail of the caudate nucleus disrupt learning, while medial temporal lobe lesions have no effect (Fernandez-Ruiz et al. 2001; Malamut et al. 1984). These results indicate that habit learning and declarative learning rely on different neural systems.

Double Dissociations Between Memory Systems

Several studies using rats have demonstrated clear double dissociations between medial temporal lobe and striatal learning systems. In a seminal study by Packard et al., rats were trained on two different versions of the radial arm maze task (Packard et al. 1989). In the radial arm maze, eight arms radiate out from a central platform, and a food reward is placed at the end of each arm. In the win-shift version of this task, arms are not rebaited as the rat eats the food, so the rat should not return to these arms during the session. The win-shift version of this task taps into foraging strategies that rats have presumably evolved to efficiently recover food over an area. Packard et al. (1989) replicated the findings from a number of studies that lesions of the hippocampus severely disrupt performance in this task (Becker et al. 1980). In order to avoid revisiting arms, the

rat must remember the locations it has just visited on that session. This would seem to require episodic memory, or memory for specific events.

In contrast to the win-shift version of the task, rats can also learn a win-stay discrimination on the radial arm maze, in which a cue consistently signals when an arm is baited, for example, the cue may be a light, which when illuminated indicates that food is present at the end of the arm. Unlike in the win-shift version of the task, the rat does not need to remember any specific event. Rather, the rat simply must learn to run down lit arms. Perhaps because it does not tap into a natural foraging strategy, rats learn this task gradually over many sessions – keep in mind that the important information learned in the win-shift task is acquired in single trial on each testing day. Packard et al. (1989) found that lesions of the striatum (the lateral caudate nucleus, which roughly corresponds to the primate putamen) impair learning of the win-stay version of the radial arm maze task. Like other habit learning tasks, this task is not affected by damage to the hippocampal system. Because the win-shift version of the task was not impaired by lesions of the striatum, there is a double dissociation between the effects of lesions on the hippocampus and striatum. This finding provides strong evidence that these two tasks depend on independent brain systems.

A similar dissociation was shown using the cross maze described above (Packard and McGaugh 1996). Rats in which the hippocampus was inactivated by an intracranial injection of lidocaine did not exhibit a preference for the location strategy after a moderate amount of training, unlike rats in the control group which received saline injections. Hippocampal inactivation appeared to prevent the expression of the location response. In contrast, rats in which the dorsolateral striatum was inactivated after moderate training showed normal expression of the location response, but when the dorsolateral striatum was inactivated after overtraining, the rats maintained the location response and did not switch to the habit response. Thus, the dorsolateral striatum must be active for expression of the gradually developing habit response.

There is also evidence in human subjects that there is a dissociation between striatal-dependent habit learning and learning that depends on the medial temporal lobe. The probabilistic classification task has been extensively studied in patient groups. For example, patients with Alzheimer's disease, which is accompanied by damage to the medial temporal lobe memory system, are able to learn the S-R associations in the probabilistic classification task (Eldridge et al. 2002). However, patients with Parkinson's disease, which affects dopaminergic input to the striatum, appear to be impaired on this task (Knowlton et al. 1996). In patients with mild Parkinson's disease, performance is not different than that of healthy control subjects. However, fMRI showed that the patients and control subjects used different neural systems during performance of this task (Moody et al. 2004). Performing the weather prediction task was associated with greater activation in the putamen in control subjects than in the patients. The control subjects also showed a decrease in activation in the hippocampus during the weather task, a finding that has been seen before. It appears that in the controls, the hippocampus is more active in the baseline condition, in which the subject is performing a very simple task (it is likely that under such conditions, the mind can wander and the subject spontaneously engages in mnemonic activity). In contrast, in the patients with Parkinson's disease, hippocampal activation was greater than the level seen in the baseline condition, consistent with the idea that these subjects were relying on declarative memory to support performance in this task. Because the habit learning system was compromised in these patients, they appear to have relied on declarative memory to perform this task.

A similar distinction between habit and declarative learning was found in the fMRI data of the study described above comparing performance of the weather prediction task under single task conditions and during distraction (Foerde et al. 2006). For the associations learned under single task conditions, performance was actually correlated with hippocampal activity in these healthy young subjects. For the associations learned under distraction, performance correlated with activity in

the striatum and not the hippocampus, suggesting that the different neural systems were responsible for learning under the two conditions. These findings also suggest that when declarative memory is functioning well, as in undistracted young subjects, it can support learning in the probabilistic classification task. However, habit learning appears to support performance when declarative memory is not strong (older subjects, distracted young subjects).

Although these dissociations based on lesions strongly suggest that different memory systems exist, these findings do not directly demonstrate that the striatal-dependent form of learning has the defining features of habit learning. While win-stay learning in rats has some of the properties of habit learning in that it is gradual and does not depend on brain regions important for declarative learning, more recent work demonstrated that learning in this task does indeed depend on S-R associations (Sage and Knowlton 2000). After training rats on a win-stay task in which they ran down lit arms to receive food, the food reward used was devalued by pairing it in the home cage with an injection of lithium chloride, which results in a learned taste aversion to the reward food. The key question was when the rats were placed on the radial arm maze after devaluation, would their behavior be modified in any way in light of their acquired aversion to the food reward. In fact, rats continued to run down the correct arms just as rapidly as they had when the food was attractive to them. This suggests that the rats had learned an association between the light and the response to run down the arm, with the reward not represented in the association. In contrast, rats trained in the hippocampal-dependent win-shift task slow down significantly when the food reward is devalued. They still employ their typical foraging strategy of efficiently traversing the maze, but their slow responding indicates that their behavior is influenced by the reward value.

Lesions of the dorsolateral striatum have been shown to prevent habit learning in instrumental procedures as well. In one study, rats with dorsolateral striatal lesions and control rats were trained under an interval schedule to press a bar for a food reward (Yin et al. 2004). Both the lesioned group

and the control group learned to make the response at roughly the same rate. However, when the reward food was devalued by pairing it with illness, the two groups behaved very differently. The performance of the control group was as expected for animals trained using an interval schedule; they continued to make the instrumental response even though the food reward was no longer attractive to them. In contrast, rats with dorsolateral striatal lesions showed a significant decrease in responding. In a sense, the lesioned rats are behaving with greater “insight” in that they are avoiding a response that is associated with undesired outcome. These data strongly make the case that the dorsolateral striatum is necessary for the development of habits. In the absence of the structure, habitual responding does not appear to develop and responding is guided by the outcome.

Basal Ganglia Loops

While the distinction between medial-temporal-lobe-dependent memory and striatal-dependent

memory is an appealing idea, it is also too simple. The striatum is organized into fairly discrete loops that include the pallidum and thalamus and different cortical regions. A seminal paper by Alexander et al. (1986) describes the architecture of these loops based on neuroanatomical findings (Fig. 2). Just as different regions of cortex have very different functions, these loops support rather different cognitive operations. Thus, it does not make sense to think of the striatum as the substrate of a particular type of memory, but rather that the different loops may serve to support different memory processes (Yin and Knowlton 2006). Lesions that affect habit learning appear to involve the dorsolateral striatum in the rat or the putamen in the primate, suggesting that the motor loop is critical for habit learning. The fact that this loop includes cortical regions that are important for motor output is consistent with the idea that habit learning involves an association with a response.

Other corticostriatal loops also appear to be important for behavior dependent on declarative

Parallel cortical-basal ganglia-cortical circuits

cingulate cortex, dl/vm dorsolateral/ventromedial, GPi/SNR globus pallidus internal/substantia nigra reticulata

learning. Damage to the dorsomedial caudate nucleus in the rat results in behavior that appears habitual under conditions in which intact rats perform based on declarative memory. In the Morris water maze, rats with dorsomedial caudate lesions have difficulty learning the location of a hidden platform and behave similarly to rats that have hippocampal lesions (Devan et al. 1999). This contrasts with the performance of rats with lesions of the dorsolateral caudate nucleus – this group is able to learn the location of the hidden platform, but has difficulty learning to swim to a cue that signals the location of the platform.

In another study using the cross maze, a dissociation was found between lesions of the dorsolateral and dorsomedial striatum (Yin and Knowlton 2004). Rats with dorsolateral striatal lesions did not show the typical tendency to run down an arm based on a stimulus–response habit after extensive overtraining. They retained the tendency to go to the rewarded location even when starting from a new arm. However, lesions placed more medially produced an effect more similar to that of hippocampal system lesions. These rats did not go to the location where they had been rewarded on previous trials, but rather, they responded based on the motor habit. The mediodorsal striatum in the rat is similar to the head of the caudate in the primate. This region is interconnected with prefrontal regions that may be more involved in goal-directed action than in habit learning (Yeterian and Pandya 1991). This loop may in fact be important for implementing actions based on the contents of declarative memory.

Electrophysiological studies have also supported the idea that goal-directed actions and habits depend on different corticostriatal loops. In nonhuman primates, performance early in training is accompanied by increased firing in the caudate nucleus. When the slope of the learning curve is steep, firing in the caudate nucleus was correlated with the slope of the learning curve. In contrast, firing in the putamen was correlated with the level of learning, with firing highest after extensive training when the monkeys were adept at the task (Williams and Eskandar 2006).

Communication Between Loops

Corticostriatal loops are often characterized as functioning independently, based to a great extent on anatomy. The thalamic targets of these loops are the same cortical regions that originated the loop. For example, in the motor loop, cortical projections from the motor cortex are directed to the putamen, which projects to relatively discrete regions of the globus pallidus that project to the ventrolateral nucleus of the thalamus. This thalamic nucleus sends its cortical projections back to motor cortex, thus completing the loop. However, it is also the case that these loops have the potential to interact based on other features of the anatomy. The thalamocortical projections terminate in multiple cortical layers, including layer III, the site of neurons that gives rise to cortico-cortical projections. Thus, the output of one loop is able to influence another through these cortico-cortical projections (McFarland and Haber 2002). In addition, there are extensive projections from the cortex back to the thalamus. For example, cortical regions involved in planning actions (pre-supplementary motor area and premotor cortex) send projections to VL, which is part of the motor loop that projects to primary motor cortex and supplementary motor cortex. By these “open loop” projections, different cortical regions can influence corticostriatal loops at the level of the thalamus.

A third mechanism by which loops can communicate is through the projections from the striatum to dopaminergic neurons in the midbrain (Joel and Weiner 2000). These dopaminergic neurons in the ventral tegmental area and the substantia nigra are the source of a major projection to the striatum. There is reciprocity in these projections, in that the different striatal regions project back to the midbrain region that supplied dopaminergic input to that region. For example, the ventral tegmental area is a major source of dopaminergic input to the ventral striatum, and the ventral striatum projects back to the ventral tegmental area. In addition, however, the ventral tegmental region also projects to other striatal regions, thereby allowing communication between the limbic loop and the other striatal loops. The dopaminergic neurons targeted by

striatal regions of the association loop (i.e., the caudate nucleus) also give rise to both reciprocal projections and projections that target the striatal regions of the motor loop (i.e., the putamen). Thus, the midbrain dopaminergic system is another means by which corticostriatal loops may interact.

An interesting feature of the striatal projections to both the thalamus and the dopaminergic system is that there seems to be a hierarchical organization in the potential interactions between loops (Joel and Weiner 2000). Cortical regions in the limbic loop project to thalamic regions in loops involved in executive function, and cortical executive regions project to thalamic regions involved in the motor loop. A similar hierarchy exists for the dopaminergic projections. The ventral striatum (limbic loop) projects to midbrain dopaminergic regions supplying all other loops, striatal regions in the executive loop send projections to dopaminergic regions supplying the executive and motor loops, and the motor striatum primarily sends only reciprocal connections back to the dopaminergic neurons that project to it. Thus, it seems that in both mechanisms of interaction, the limbic loop has the potential for greater influence over the other loops, loops involved in executive function can influence those involved in motor function, while the motor loops have limited ability to influence the other loops.

The reciprocity of connections in the motor loop has been incorporated into computational models of learning in the striatum. Dopaminergic input plays an important role in providing a reinforcement signal in these models. The actor-critic architecture (Barto et al. 1983) captures this role of reinforcement, by postulating a “critic,” in the form of dopaminergic input, that provides the “actor,” in the form of striatal neurons, with a reinforcement signal based on whether success has been obtained. One challenge to these models is the problem of credit assignment – the consequences of an action are often delayed. These models are able to address this challenge based on the fact that the dopaminergic input to each region of the striatum arises from cells in that same zone that receives input from that striatal region. This reciprocity means that dopaminergic

activity will strengthen the response just preceding it. On subsequent trials, dopaminergic activity will then occur during this response, thus strengthening the response just before it. Through this recursive mechanism, activity in the dopaminergic neurons becomes a predictive signal for reinforcement (Houk et al. 1995).

Plasticity in the Striatum

One question that arises in discussing the role of the neostriatum in learning is where the plastic changes that support learning occur, and whether the physiological mechanisms of this plasticity are similar to or different than those that have been described in the medial temporal lobe system. As in the hippocampus, long-term potentiation (LTP) occurs in the striatum, and this phenomenon has been considered a model system for the formation of habit memories (Reynolds et al. 2001). In addition, long-term depression (LTD) can also be induced in the striatum. High-frequency stimulation of the cerebral cortex induces LTP or LTD at the corticostriatal glutamatergic synapses. Dopamine is important for the induction of plasticity in the striatum. LTP or LTD cannot be readily induced in slices from animals in which dopamine is depleted (Calabresi et al. 1992; Kerr and Wickens 2001).

Unlike in the hippocampus, where LTP has been studied more extensively than LTD, striatal LTD has received more attention in the past than LTP. High-frequency stimulation trains that produce LTP in the hippocampus produce LTD in the striatum. In fact, LTP was not initially obtained in the striatum unless magnesium was absent. It appears that the facilitative effects of the lack of magnesium were mediated by dopamine-NMDA receptors, which are normally blocked by magnesium, and can be activated on presynaptic dopamine terminals, leading to an increase in dopamine levels (Wickens and Arbuthnott 2005).

More recently, the role of dopamine in striatal plasticity has been shown to be complex. The different types of dopamine receptor (D1 and D2) are on different populations of medium spiny neurons in the striatum. Both receive dopaminergic input from the substantia nigra, but these two classes of neurons participate in two different

striatal output pathways: D1 receptors are on neurons in the direct pathway, and D2 receptors are on neurons in the indirect pathway that includes the globus pallidus external and the subthalamic nucleus (Gerfen et al. 1990; Fig. 3). On both of these pathways, glutamate input from the cortex is excitatory, but the net effect of the two pathways is different. Exciting the direct pathway serves to remove tonic inhibition in the thalamus, which thus is excitatory to the cortex. Exciting the indirect pathway has the net effect of strengthening this tonic inhibition. Thus, striatal plasticity can lead to either increased or decreased cortical activity.

In a study examining the role of dopamine in striatal plasticity, Shen et al. (2008) assessed LTP and LTD in both the direct and indirect pathways. On striatal medium spiny neurons that have D1 receptors (the direct pathway), LTP can be generated from pairing presynaptic activity with postsynaptic depolarization. When D1 receptors are blocked, this pairing leads to LTD. In medium spiny neurons with D2 receptors (the indirect pathway), LTP and LTD can be induced, depending on the timing of the pre- and postsynaptic stimulation. Blocking D2 receptors disrupts LTD, while increasing D2 receptor activation results in LTD under conditions in which LTP is normally induced. Thus, under low dopamine

levels, when only higher-affinity D2 receptors are activated, plasticity is bidirectional in neurons containing D2 receptors, while only LTD is enabled in neurons containing D1 receptors. However, when dopamine levels rise, as when a reinforcing stimulus is present, LTP can be induced in neurons containing D1 receptors, while those containing D2 receptors will be biased toward LTD.

These findings point to an important role for dopamine in the control of plasticity in corticostriatal synapses and suggest that medium spiny neurons with D1 and D2 receptors play different roles in learning. When D1 receptors are activated, as in the case of a large, unexpected reward, efficiency will increase in corticostriatal synapses on neurons containing D1 receptors, thus strengthening the direct pathway, leading to greater excitation of the cortex. However, when dopamine is at a tonic level, experience would result in enhancement only in corticostriatal synapses on neurons containing D2 receptors, thus strengthening the indirect pathway, leading to increased tonic inhibition of cortex (Shen et al. 2008). In addition to differences in the role of different corticostriatal loops in behavior, conditions within each loop (e.g., dopamine levels) control the net effect of that loop on its target cortical region.

Basal Ganglia: Habit Formation, Fig. 3 Direct and indirect pathways in the basal ganglia.
Abbreviations: *GPI* globus pallidus internal, *ctx* cortex, *GPE* globus pallidus external, *STN* subthalamic nucleus

It is tempting to think of these two mechanisms of plasticity of supporting learning of actions and habits; early in learning, new associations are formed in the direct pathway when dopamine signals the presence of reinforcement. As practice increases and reinforcement becomes expected, dopamine levels decrease and performance becomes increasingly controlled by the indirect pathway, characterized by a lack of flexibility and insensitivity to devaluation.

The interplay between the direct and indirect pathways is incorporated into models of dynamic gating by the basal ganglia (Frank et al. 2001). When the direct pathway is activated, there is a disinhibition of cortex, enabling the updating of working memory and flexibility. Activity in the indirect pathway has the opposite effect – it increases inhibition in the cortex, thus favoring maintenance. In this way, the architecture of the cortico-basal ganglia system balances between the conflicting demands of updating vs. maintaining behavior. Furthermore, the existence of parallel loops with relative independent neuronal circuits allows the updating of some information, but not others according to these gating models (O'Reilly and Frank 2006).

Interactions Between Learning Systems

What does the anatomy and neurophysiology of the striatum suggest about how different systems for learning interact? The loop architecture suggests parallel modes of learning; loops involving the caudate and prefrontal cortex may be more involved in voluntary action than loops involving the putamen and motor cortex. Learning may proceed in these loops in parallel, with behavior controlled by whichever loop is the most effective at influencing the structures supporting behavioral output. While the limbic and associative loops are able to influence the effectiveness of the motor loop, there is substantial independence – one could be learning a goal-directed action while also strengthening a habit based in the motor loop. By this view, learning a goal-directed action does not impede the learning of a habit or vice versa. On the other hand, the antagonistic relationship between plasticity in the direct and indirect pathways suggests that at some level there is

competition between types of learning. Linking plasticity in the direct and indirect pathways with behavior is essential for understanding the significance of striatal architecture.

If different memory systems acquire memories in parallel, competition is likely to occur at the level of control for behavioral output. It may be that the selection is based on the strength of the learned representation. Declarative memories may be formed faster and thus control behavior early in training, while habits accumulate associative strength more slowly, but eventually become dominant. For example, in the cross-maze task described above, the correct response according to a declarative memory for the location of reward is incompatible with the stimulus–response-based habit to turn in one direction in that these two responses lead to different places when a new starting location is used at the opposite end of the maze. Thus, the control of behavioral output may be determined by relative memory strength, which would likely change with practice level. If behavioral output is determined by memory strength, the critical question is how the “strongest” memory is determined that will control behavioral output. Of course, in most situations, declarative memory and habit would presumably lead to the same outcome. However, situations such as the cross maze can bring these two systems into conflict. This could be seen in the “real-life” example of making a turn along a well-learned route when in fact you had intended to turn the other way at the intersection to go to a different destination on this day. Responding based on habit and on declarative memory will lead to opposing responses.

Given that responses based on declarative memory and habit learning can differ, it is important to determine the conditions that favor the use of one representation over another. Our awareness is based on declarative knowledge. Thus, when we are consciously aware of responding based on memory, we are using declarative memory. However, when awareness is otherwise occupied, behavior is more likely to depend on habits due to their relative insensitivity to working memory load (Foerde et al. 2007). Conditions that occupy or reduce working memory resources, such as

anxiety, depression, and fatigue, may bias behavior toward the learning and retrieval of habits. Individuals suffering from depression and anxiety exhibit impaired working memory (Rose and Ebmeier 2006; Samuelson et al. 2006). In addition, even mild forms of depression are accompanied by a tendency to ruminate and have intrusive thoughts, thus squandering working memory resources (Joormann and Gotlib 2008). Emotional factors may thus play a role in the type of representations that are learned and that control behavior. The implications of this idea are that people under stress or preoccupied may be more likely to fall back on old habits even when an updated approach is warranted.

Habit learning is a form of instrumental learning, in that making the response is necessary to obtain the outcome during training. In Pavlovian conditioning, pairing of the conditional stimulus (e.g., a buzzer) and an unconditional stimulus (e.g., food) leads to the conditional stimulus eliciting a conditional response (e.g., salivation). The response has no bearing on whether the unconditional stimulus is received. Interestingly, these two different forms of learning interact. Presenting cues that have been conditional stimuli in Pavlovian conditioning can act to facilitate the transfer of actions to habits. This phenomenon has been discussed most extensively in the context of addiction, where behaviors such as drug taking become compulsive and persist despite the desire to cease. The transition from voluntary action to habitual responding is thought to characterize, at least in part, the transition from drug user to drug addict (Everitt et al. 2001). During drug use, Pavlovian conditioning occurs that associates drug-related cues and contexts (conditional stimuli) with the physiological effects of the drugs (unconditional stimuli). In animal models of addiction, the presence of these conditional stimuli leads to faster learning of an instrumental response (Pavlovian-instrumental transfer) but also a faster transition from voluntary responding to habitual stimulus–response responding. This effect of Pavlovian conditioning may result from the influence of limbic loops of the striatum on other loops (Everitt and Robbins 2005).

Conclusion

Although we are often not aware of our habits, they arguably have a greater influence on our ongoing behavior than declarative memories do. Our habits provide a backdrop to our conscious behavior. Psychiatric disorders such as addiction and compulsive behaviors are fundamentally problems with habits that are intrusive in daily life. Thus, how habits are formed and how they interact with declarative memories are key questions in understanding both normal and abnormal behaviors.

Basal Ganglia: Mechanisms for Action Selection

Mark D. Humphries
Faculty of Life Sciences, University of
Manchester, Manchester, UK

Definition

The basal ganglia are an interconnected circuit of fore- and midbrain nuclei common to all extant vertebrates, including the lamprey, which

diverged from the main vertebrate line approximately 560 MYA. Moreover, there are analogous structures in birds and bony fish. The preservation of this circuit implies a crucial operation that solves a problem common to all vertebrates. While many functions for the basal ganglia have been proposed, our current best theory to unify these ideas is that this circuit solves the common problem of action selection. Informally put, this is the problem of how to decide what to do next.

Detailed Description

Why Action Selection?

The necessity of a mechanism for action selection is imposed by the strong constraint that complex animals have a final common motor pathway: the connections of the spinal cord and the number of muscle groups limit the set of actions that can be expressed simultaneously. Some mechanism is required to reduce the repertoire of currently available actions to just those actions capable of simultaneous expression. Given the constraints of biological tissue, a central rather than distributed selection mechanism is likely the preferred solution implemented by a neural substrate (Prescott et al. 1999). Briefly, the argument runs as follows. Typically, distributed selection mechanisms, formed by reciprocal, inhibitory links between n behavior-representing nodes, contain $n(n - 1)$ links and grow as $2n$ for every additional node. By contrast, a central selection device which is reciprocally connected with all n nodes (thus allowing control over the expression of each node's represented behavior) requires just $2n$ links and grows by 2 for each additional node. Thus, a central selection device is more economical in both the number of connections required and the cost of adding nodes. Such economy of wiring appears to be a priority for the central nervous system (Cherniak 1994).

The basal ganglia appear to fulfill the criteria for such a central mechanism (Redgrave et al. 1999). The main input nucleus, the striatum, receives input from every region of cortex, from primary visual, auditory, and somatosensory cortex, through motor cortices, to the subregions of

prefrontal cortex. It is thus in a position to integrate sensory information, current motor commands, planning, and goals into representations of the relative importance, or *salience*, of each action. The output of the basal ganglia targets regions in the thalamus and brain stem that underpin the execution of different actions. The basal ganglia are thus also in a position to directly control the activity in neural systems responsible for executing actions.

The idea that the basal ganglia perform action selection is also a potential solution to the long-standing paradox of their role in controlling movement (Marsden and Obeso 1994). Activity in the basal ganglia is strongly correlated with movement onset and parameters of that movement, and stimulation of regions of the striatum can evoke discrete, smooth limb movements (Alexander and DeLong 1985). Yet lesions of basal ganglia nuclei in animal studies or in Parkinson's disease patients to alleviate their symptoms do not clearly impair the initiation of movement (Marsden and Obeso 1994). The theory that the basal ganglia are necessary to control the choice of actions explains how movement-related activity can arise yet not be needed to directly generate movement.

How Can the Basal Ganglia Circuit “Select”?

While the basal ganglia's inputs and outputs position these nuclei to potentially act as a central selection mechanism, the key evidence in favor of this idea is that their internal circuitry is seemingly designed to implement a selection process. Figure 1 illustrates the basic circuitry of the basal ganglia as currently understood. The original proposals for how the internal circuitry of the basal ganglia may implement a selection process envisioned a division of labor between the “direct” and “indirect” pathways (Albin et al. 1989; DeLong 1990; Alexander and Crutcher 1990). The direct pathway was proposed to be responsible for selection through a process of *disinhibition* (Chevalier and Deniau 1990), illustrated in Fig. 1. The output nuclei of the basal

ganglia are continuously active, providing a source of constant (or “tonic”) inhibition to their targets. A sufficiently strong input signal from cortex can elicit activity in a population of projection neurons in the striatum, which in turn converge on and temporarily inhibit the firing of neurons in the output nuclei. This pause in tonic firing is then interpreted as the signal for selection.

This disinhibition process has been worked out in detail for the control of voluntary eye movements, or *saccades*, in primates (see Hikosaka et al. 2000). Phasic activity in the caudate region of the striatum precedes saccade initiation and is time-locked to a decrease in activity in a subset of SNr neurons. The SNr projects to the intermediate layers of the superior colliculus, which contains a retinotopic map – neurons are laid out in a sheet that represents coordinates of gaze direction. A buildup of neural activity on this map drives the brain stem circuitry that controls the eye muscles and moves gaze to the location signaled by the map. The pause in SNr activity precedes and appears to be required for the buildup of activity in the retinotopic map of the superior colliculus. Conversely, continuously inhibiting SNr activity results in the inability to suppress saccades, as though every eye movement motor command was being executed (Hikosaka and Wurtz 1985). Thus, the direct striatum-SNr pathway likely controls the selection of saccade direction through a process of disinhibition.

Multiple Mechanisms Contributing to Action Selection

Computational models have provided quantitative tests of these ideas, revealed the further necessary mechanisms for successful selection, and shown how these mechanisms are implemented by components of the basal ganglia circuit. The box-and-arrow model accounts of “direct” pathway control of selection focussed on the flow of signals necessary to select one input and so omitted two crucial aspects of a selection process: how to resolve the *competition* between multiple action-representing inputs and how to *switch* from a

Basal Ganglia: Mechanisms for Action Selection, Fig. 1 Basal ganglia circuit and selection. The striatum receives input from most of cortex and many thalamic nuclei; a subset of the same regions project to the subthalamic nucleus (STN). The striatum is split into two populations of projection neurons according to whether they predominantly express the D1 or D2 receptor for dopamine: the populations and their targets respectively form the “direct” and “indirect” pathways. The globus

pallidus external segment (GPe) projects within the basal ganglia; the globus pallidus internal segment (GPi) and substantia nigra pars reticulata (SNr) project to targets in the brain stem and thalamus. The cartoon spike-trains illustrate the basic process of disinhibition in the “direct” pathway: continuous firing from the GPi/SNr tonically inhibits their targets; brief phasic activity in striatum, driven by coordinated cortical activity, can pause that tonic inhibition, allowing the targets to fire

currently selected action to another, more salient, action.

Competition

To be able to resolve a competition between actions first requires a substrate for separately representing each of those actions. A long-standing concept in basal ganglia research is the existence of parallel loops running through the basal ganglia (Alexander et al. 1986; Middleton and Strick 2000). At the macroscopic level, independent *domains* of the basal ganglia have been identified by the closed send-and-return loops originating in broad cortical regions (Alexander et al. 1986). Each macroscopic domain is thought to subdivide into a further large set of discrete parallel loops, termed *channels* here to distinguish them from the macroscopic-scale loops. For

example, the somatotopic map found within the striatal motor domain is maintained throughout the basal ganglia’s intrinsic circuitry, such that there are separate channels for arm, leg, and face representations (Alexander and Crutcher 1990; Romanelli et al. 2005). Similar topographic maps have been proposed for the other macroscopic loops (Alexander and Crutcher 1990). Moreover, within these limb representations, there may be additional discrete channels corresponding to particular movements, demonstrated in striatum by microstimulation (Alexander and DeLong 1985) and markers for metabolic activity during behavior (Brown and Sharp 1995), and to repeated representations of body map locations (Brown et al. 1998). Computational models of the basal ganglia have proposed that it is these channels which form the basis for

action representation, and so the resolution of competition is expressed by the selection of a particular channel in the output of the basal ganglia (Gurney et al. 2001a).

The basal ganglia circuit contains a number of mechanisms potentially suited to resolving competition between competing channels. One candidate mechanism is the inhibitory network formed by the local axon collaterals of the projection neurons in striatum, which could underpin a winner-takes-all competition between input signals (Alexander and Wickens 1993). A problem with this idea is that these feedback connections are weak and asymmetric so that a classical winner-takes-all competition is unlikely to be supported (Plenz 2003). Even if it is, because of the range of the local axon collaterals, this interaction can only extend over a short distance in the striatum, on the order of 200–300 μm (Wickens 1997; Humphries et al. 2010). Consequently, any dynamics within striatum are likely only to resolve very local competitions between cortical inputs (Gurney et al. 2001b).

The competition between a set of channels most likely takes place at the inputs to the basal ganglia output nuclei, the SNr and GPi. As shown in Fig. 2, each population of striatal neurons projects to a corresponding population of SNr or GPi neurons, but the output of each population of STN neurons also contacts neighboring channels in SNr and GPi. This creates an off-center, on-surround network ideal for resolving competition between action signals (Mink 1996; Gurney et al. 2001a; Humphries et al. 2006; Leblois et al. 2006) as illustrated in Fig. 2.

A key insight from computational models is that the on-surround effect of the combined STN output can lead to SNr/GPi activity in many channels increasing above their tonic rate at the time of action selection – a phenomenon termed *contrast enhancement*. This makes functional sense: an enhanced tonic inhibitory signal being output from most channels indicates a definite non-selection of that action. However, when observed in experimental data, such increases in activity, time-locked to movement, have been interpreted as encoding that movement. By contrast, the models show how an increase in SNr/GPi neuron

Basal Ganglia: Mechanisms for Action Selection, Fig. 2

Competition resolution and switching by the basal ganglia. Actions are thought to be represented in parallel loops or channels running throughout the basal ganglia, with each action's relative salience computed by inputs from cortex. The bars in each box are cartoons of activity of each population in each structure. Each striatal population projects to a corresponding SNr/GPi population, providing focussed inhibitory input; STN output is comparatively diffuse, projecting across neighboring channels and providing diffuse excitatory input. The result is an off-center, on-surround network in SNr/GPi, where the strongest signal from among the striatal populations is able to inhibit the firing of its target SNr/GPi population, while at the same time the combined excitatory output of the STN counteracts the effect of the other inhibitory signals from striatum

output time-locked to an action does not encode that action, but rather encodes the simultaneous nonselection of another potential action. Moreover, the models show that the number of neurons with such increased activity, time-locked to an action, will be in the majority and hence will appear more frequently during neural recordings (Humphries et al. 2006).

Switching

Once action selection has been achieved, then action switching is required: the sudden

availability of a more salient action through changes in the environment or the animal's needs should terminate the ongoing action and then switch to selecting the new, more salient alternative. Computational models have again shown how the same off-center, on-surround design naturally handles this: the new input further increases the STN output, canceling selection of the current action, while the corresponding new, strong inhibitory signal from striatum inhibits its target population in GPi/SNr (Gurney et al. 2001b; Humphries and Gurney 2002). Embedding these models in mobile robots has shown how smooth behavioral sequences naturally emerge from the changing saliences of each action, without the need for explicit storage of sequences (Khamassi et al. 2005; Prescott et al. 2006).

The “Indirect” Pathway: Prevention of Selection and Scaling of Selection

The contribution of the “indirect” pathway to selection has been more difficult to unravel. The original box-and-arrow models proposed that this pathway acts to counteract the selection of an action: increased inhibition of the GPe by its striatal inputs would lead to enhanced STN output to SNr/GPi, thereby counteracting inhibition they were receiving in the direct pathway (Alexander and Crutcher 1990). Consequently, it was proposed that any imbalance between the relative strengths of the direct and indirect pathways could lead to movement disorders (Albin et al. 1989). Recent experimental studies have shown how selectively activating the striatal D1 or D2 projection neuron populations does indeed lead to opposite effects on behavior: stimulation of D1 projection neurons facilitates behavior, whereas stimulation of D2 neurons suppresses ongoing behavior (Kravitz et al. 2010).

The computational models of Frank and colleagues (Frank et al. 2004; Frank 2005) have extended these ideas by proposing that recruitment of these “go” and “no-go” pathways by cortical input during learning would depend on

the level of available dopamine. They showed these models could account for a range of learning biases exhibited by Parkinson's disease patients, providing support for the go versus no-go competition between the direct and indirect pathways.

A further mystery was the role of STN feedback to the GPe (Fig. 1). An analysis by Gurney et al. (2001b) showed that this negative feedback loop provided *capacity scaling* for action selection. Without a loop between STN and GPe, the diffuse STN output means that the total excitatory input to the SNr/GPi would grow in proportion to the number of active inputs to the basal ganglia; with a sufficient number of inputs, the excitatory input would grow large enough to overwrite all focussed inhibition from the striatum and prevent any selection. However, the negative feedback loop ensures that the STN output is scaled to the number of active inputs: the more the inputs, the more the STN output tries to grow, but is held in check by the GPe output which is itself a function of the STN output. In this way, the basal ganglia's capacity can scale and so can operate as a selection mechanism independently of the number of currently competing channels.

- ## Basal Ganglia: Songbird Models
- Arthur Leblois¹ and Ran Darshan²
- ¹Institut des Maladies Neurodégénératives, UMR, Université de Bordeaux, Centre National de la Recherche Scientifique, Bordeaux, France
- ²HHMI, Ashburn, VA, USA
- ## Definition
- Songbirds use learned vocalization to communicate. During initial song acquisition, juvenile birds reproduce adult vocalizations through a

process very similar to speech learning in babies. Initial “babbling” vocalizations are turned into a faithful copy of the tutor song through a trial-and-error process that relies on a basal ganglia-thalamo-cortical circuit (► [Basal Ganglia: Overview](#)).

Detailed Description

Songbirds use learned vocalizations to communicate during courtship or aggressive behaviors. These vocalizations, called song, require fast coordination of laryngeal and respiratory muscles. Songbirds learn their song as juveniles through a long process comprising two sequential phases: the juvenile first listens to and memorizes one or more tutor songs, and then uses auditory feedback to match its song to the memorized model through trial-and-error.

While song production is under the control of two cortical nuclei, HVC (used as a proper

name) and the robust nucleus of the arcopallium (RA, Fig. 1a), song learning and plasticity strongly rely on the basal ganglia (BG, Scharff and Nottebohm 1991). Interestingly, songbirds display a specialized portion of their BG-thalamo-cortical circuitry, called the anterior forebrain pathway (AFP), devoted to song learning and plasticity (Fig. 1b; Brainard and Doupe 2002), and homologous to the mammalian motor BG-thalamo-cortical loop (Fig. 1c; Reiner et al. 1998). In particular, the song-related BG nucleus Area X receives dense dopaminergic innervation and contains neuron types homologue to both the mammalian striatal and pallidal neurons, forming similar circuits (Farries and Perkel 2002; Leblois et al. 2009). Songbirds and their specialized BG-thalamo-cortical loop devoted to a naturally learned complex sensorimotor task offer a unique opportunity to study the function of the BG in skill learning and execution (Doupe et al. 2005).

Basal Ganglia: Songbird Models, Fig. 1 The song-related BG-thalamo-cortical network in songbirds, and its homologue circuit in mammals. BG Functions in Songbirds: Experimental Background

The BG loop in songbirds is necessary for song learning but not for song production per se. BG neurons respond selectively to playbacks of the bird's own song (Doupe and Solis 1997), and were initially thought to convey auditory feedback signals to be compared with a stored template of the tutor song. However, no neuronal correlate of such comparison can be found in the BG-thalamo-cortical loop (Leonardo 2004). Auditory feedback-related activity has however been reported in upstream cortical nuclei (HVC), where similar neuronal responses can be observed in response to syllable production or playback ("mirror neurons," Prather et al. 2008). During song production, the BG-thalamo-cortical loop introduces motor variability allowing vocal exploration (Kao et al. 2005; Ölveczky et al. 2005, for comparison to its role in mammals, see ► ["Basal Ganglia System as an Engine for Exploration"](#)), as needed in a reinforcement learning (RL) framework (see also ► ["Reinforcement Learning in Cortical Networks"](#)), and can guide adaptive changes in song to minimize errors (Andalman and Fee 2009). Moreover, dopaminergic neurons projecting to the song-related BG nucleus (Area X) provide an online evaluation of current singing behavior (Gadagkar et al. 2016) and the dopaminergic input to Area X is necessary for song plasticity (Hoffmann et al. 2016). These data are consistent with the implementation of a reinforcement learning mechanism in the BG-thalamo-cortical loop in birds (Fee and Goldberg 2011), just as it has been proposed also in mammals (Doya 2000; ► ["Basal Ganglia: Mechanisms for Action Selection"](#)).

Reinforcement Learning in Songbirds

Most models of BG-dependent learning in songbirds are in an RL framework (but see Ganguli and Hahnloser 2013). In these models, a timing signal is assumed to be produced in HVC, where output is sent to the BG to serve as a clock input during learning. Based on this clock input, the RL

circuit learns to produce the correct motor gestures at each time step. In the RL framework, the agent learns to correlate random motor explorations with fluctuations in a reward signal in order to select motor patterns that lead to the highest reward. For example, changes in the song (the motor output) that increase the amount of expected reward should be implemented, whereas song changes leading to lower expected reward should be discarded. Implementation of such RL framework in the song-related neuronal circuitry must include four components: (1) an "actor" that produces the song, (2) a mechanism for exploration, implemented in a variability circuit (Fee and Goldberg 2011), a searcher (Doya and Sejnowski 1998), or an experimenter (Fiete et al. 2007), which may be based on a recently proposed mechanism for generating correlated variability (Darshan et al. 2017), (3) a comparator circuit, or "critic" (Doya and Sejnowski 1998) that computes the reward signal by evaluating the produced song with respect to the memorized template, and (4) a learning mechanism to modifies motor output with time.

Different Models of Song Production and the Involvement of the AFP

In a first RL model for song learning, Doya and Sejnowski (1998) proposed that nucleus LMAN could act as the "searcher," perturbing each synaptic connection between HVC and RA independently, while the BG would evaluate each produced song using tutor-selective neurons (Fig. 2). This weight perturbation algorithm results in a plasticity in HVC-RA synapses after each epoch, that is, at the end of song rendition.

Fiete et al. (2007) elaborated on Doya and Sejnowski model in a biologically realistic network of spiking neurons. While the location of the critic in their model was only speculative, the other elements of the model were similar to Doya and Sejnowski (1998): plasticity took place in HVC-to-RA synapses and LMAN was again the search element, called "experimenter." Besides its realistic nature, their model differs from previous models by utilizing a new learning

Basal Ganglia: Songbird Models, Fig. 2 Architecture of the basic song RL models (Doya and Sejnowski 1998; Fiete et al. 2007). Dashed box represents the search/experimenter element. Gray box represents the critic. Plastic synapses are displayed in wide black arrows

Basal Ganglia: Songbird Models, Fig. 3 Architecture of the more complete song RL model including BG circuits (Goldberg and Fee 2011). Arrows and color code as in Fig. 2

algorithm relying on node perturbations, where LMAN neurons perturb the activity of RA neurons instead of their synaptic efferences from HVC (Fig. 2), and an online reward signal during song. Using such a realistic learning algorithm, the circuit learns a simple song in a biologically plausible number of song renditions.

Recently, Fee and Goldberg (2011) have published a conceptual model that argues that the AFP is not a comparator but is rather biasing the motor system (Fig. 3). Based on ideas taken from the classical implementation of RL in the mammalian motor BG loop (Wickens et al. 2003), they hypothesize that the song-related BG receives an evaluation signal from neuromodulators such as dopamine, and uses this signal to select the relevant motor gestures at the right time. As in mammals, the avian BG-thalamo-cortical circuit and the descending connections to motoneurons form a topographically organized circuit displaying segregated “motor channels.” In this model, LMAN again drives variability in song production, and sends a copy of this variability signal to striatal neurons. Receiving a convergent timing signal (or “context”) from HVC, and a global

dopaminergic reward signal, the striatal neurons are considered as coincidence detectors and select the right motor variation in the right context in each motor channel. Synaptic plasticity at HVC-to-X synapses then allows the acquisition of correct motor biases. Although this model has not been computationally implemented yet, it is algorithmically similar to Fiete et al. (2007), with the learning occurring at HVC-to-X synapses instead of HVC-to-RA synapses.

Template Comparison, Efference Copy, or Inverse Model?

In the RL models discussed above, a global reward signal evaluating auditory feedback quality is delivered by the critic. Because of delays that are inherent in the transformation of neural activity into vocal gestures and in the auditory processing of produced sounds, the reward signal is necessarily delayed with respect to the neuronal activity underlying the rewarded gesture. In other words, the reward is likely temporally imprecise.

Basal Ganglia: Songbird Models, Fig. 4 Schematic description of the efference copy learning (a) and song learning (b) in the Troyer and Doupe model (2000). Blue

arrows represent the motor-auditory transformation in (a) and the “efference copy” of this transformation in (b). Other color code as in Fig. 2

To overcome this delay problem, an eligibility trace can be used (Doya and Sejnowski 1998; Fiete et al. 2007).

A different solution for the delay problem was given by Troyer and Doupe (2000; Fig. 4). While they still assume that the AFP evaluates the song, they propose that evaluation is based on an efference copy of the song’s motor program. In a first stage, a motor-to-sensory mapping is built by implementing Hebbian learning at synapses between HVC neurons projecting to RA (HVC_{RA}), assumed to be motor, and HVC neurons projecting to Area X (HVC_X), assumed to be auditory. The bird thereby learns to predict auditory consequences of its motor gestures. Such a mapping is usually termed a “forward model,” or “efference copy.” During this initial learning stage, the plastic connection (thick black arrow in 4a) is modified to implement such efference copy. After implementing the motor-to-sensory transformation (blue arrow in Fig. 4b), the auditory feedback to HVC_X is switched off by adaptation mechanisms and the AFP neurons displaying tuned responses to tutor song evaluate the vocal production through the comparison between the efference copy and a representation of the tutor song. In this stage the AFP acts like a

critic. As in Doya and Sejnowski, synapses within RA and from HVC_{RA} to RA are modified to optimize song.

The last model, proposed by Ganguli and Hahnloser (2013), consists of two brain areas, an auditory area and a motor area, represented in a very simplified framework. Their model relies on three already mentioned assumptions: production of highly variable vocalization during learning, gating mechanisms for specific synaptic inputs, and a synaptic mechanism for Hebbian learning (see ► “Hebbian Learning”). It is not based on an RL framework and no evaluation of the song, or comparison with the tutor’s song is needed. Instead, the bird learns an inverse model through the mapping of sensory (auditory) commands to the appropriate motor commands, relying solely on Hebbian learning. First, random vocalizations induce Hebbian learning between auditory and motor representation of the produced sounds (Fig. 5a), creating an inverse model. Secondly, the song is produced by gating auditory feedback inputs to the auditory area and playing the template, stored in the recurrent synapses inside the auditory area (Fig. 5b). Interestingly, sensory neural responses to song playback mirror motor-related activity recorded during singing in nucleus

Basal Ganglia: Songbird Models, Fig. 5 Architecture of the inverse model for song learning (Ganguli and Hahnloser 2013). Wide blue arrows represent the motor-auditory transformation. (a) Learning the inverse model (in wide black). (b) Song production. After learning the inverse model (dashed blue arrow), auditory feedback and the searcher element are gated

LMAN (Giret et al. 2014). Such matching of mirroring offsets and loop delays is consistent with the implementation of an inverse model in or upstream from the cortico-basal ganglia loop.

Definition

Models of neuron types of the striatum, which include details of ion channels and neuron morphology.

Detailed Description

Striatal Function in Disease and Health

The striatum is the main input structure of the basal ganglia and is implicated in habit learning, addiction, and neuropathologies such as Parkinson's disease and Huntington's disease. Parkinson's disease is a motor dysfunction caused by degeneration of dopaminergic neurons that project strongly to the striatum. Huntington's disease is another motor dysfunction caused by degeneration of a subset of the neurons in the striatum. Experiments in both humans and animals have demonstrated that normal habit learning involves the striatum, and changes in striatal neural activity are observed consequent to cortical glutamatergic activity (in response to environmental stimuli or motor activity) and dopamine release in response to reward.

Cell Classes in the Striatum

The projection neurons of the striatum are the spiny projection neurons (SPNs) which make up the majority (90–95%) of the neurons and are subdivided into two classes: those with dopamine D1 receptors which co-release substance P and dynorphin and those with dopamine D2 receptors which co-release mu-opioids. Three other classes of interneurons have been extensively studied: the GABAergic fast-spiking interneurons (FSIs) which are connected by gap junctions, the GABAergic neuropeptide Y-positive (NPY) interneurons which also produce nitrous oxide and are characterized electrophysiologically as low-threshold-spiking interneurons (LTSIs), and the acetylcholinergic (ACh) interneuron, also called the tonically active neuron because of its spontaneous and regular firing pattern. An additional NPY-expressing interneuron type has been recently characterized as a neurogliaform (NGF) interneuron which exhibits distinctly slow inhibitory kinetics in its synapses to SPNs. More recently it has been possible to characterize a set of tyrosine hydroxylase neurons using transgenic expression systems. These neurons exhibit four different firing patterns, but their role in striatal circuits remains to be elucidated. The GABAergic interneurons are positioned to modulate the timing and pattern of firing of the projection neurons of the striatum. In addition, their interconnections via both chemical and electrical synapses may play a role in synchronization. The acetylcholinergic neurons modulate dopamine release from the substantia nigra and modulate striatal neuron properties through pre- and post-synaptic metabotropic receptors.

One of the compelling questions about striatal function is the role of the D1 versus D2 SPNs. The prevalent theory regarding Parkinson's disease is that dopamine increases excitability of D1 SPNs and decreases excitability of D2 SPNs. The absence of dopamine leads to overactivity of the D2 SPNs which tend to inhibit voluntary movement. Thus, some striatal models have been developed to evaluate which characteristics of SPNs can explain the difference between D1 and D2 neurons and the effect of dopamine. Both neuron

classes exhibit a characteristic bimodal membrane potential distribution during anesthesia and sleep, known as upstates and downstates. Though the significance of this activity is still unclear, several models have investigated which neuron mechanisms underlie this activity. Both normal habit learning and the overly strong habit learning of drug addiction likely involve synaptic plasticity of the SPNs; thus several models have investigated the control of calcium concentration during synaptic and neuronal activity, which are essential for synaptic plasticity.

Simple SPN Models

Some models contain only a small subset of cellular components and attempt to reproduce a specific cellular phenomenon. The purpose of these types of models is to explain cellular behavior using the smallest possible subset of mechanisms. This has the dual advantage of minimizing the number of free parameters while demonstrating that specific channels/interactions are required. It has the disadvantage of being unable to demonstrate possible alternative mechanisms which might explain the data. Examples of this approach are Gruber et al. (2003) which use two potassium channels and one calcium channel to test whether the known effects of dopamine on these channels affect membrane bistability and Mahon et al. (2000) which implement detailed channels but a single compartment to show that the slow A-type potassium channels in SPNs confer short-term facilitation of excitability. Another model (Koos et al. 2004) represents the complete morphology but contains no voltage-dependent channels. This model shows that morphological characteristics, such as electrotonic distance, can account for the difference in amplitude of inhibitory postsynaptic potentials (IPSPs) produced by FSIs compared to SPNs. Simple modeling approaches have also been extended to model striatal network activity. For instance, McCarthy et al. (2011) demonstrated that inhibitory GABAergic currents and M-type potassium currents can interact to produce beta oscillations symptomatic of Parkinson's disease in the striatal network, using single compartment models with detailed channels.

Complex SPN Models

The more complex models contain many cellular features (Table 1) and attempt to reproduce many characteristics of voltage and/or calcium waveforms. The advantage of this approach is being able to isolate specific channels or morphological characteristics within the context of many cellular characteristics to demonstrate the necessity or sufficiency of a mechanism in replicating an experimental finding. In addition, these complex models can be used to evaluate interactions between mechanisms and whether the proposed mechanism exhibits the same function or characteristics in a different context, e.g., in vivo versus in vitro. Ideally, these models can be reused to explain new data with minimal change. The disadvantage of this approach is having numerous free parameters, and the complexity can sometimes hinder the ability to illuminate concepts.

The first complete SPN model (Wolf et al. 2005) used the NEURON simulation software to model a neuron from the ventral striatum (nucleus accumbens). This model replicates many of the characteristics of SPNs, such as the long delay to action potential at rheobase and the low frequency of spiking. The model was used to test the effects of the NMDA/AMPA ratio on entrainment to oscillation (Wolf et al. 2005) and later to test the effects of dopamine modulation on synaptic integration (Moyer et al. 2007). The inwardly rectifying potassium current (Kir) was retuned (Stephen and Manchanda 2009) and implemented in this model to investigate the role of inactivating Kir in SPN excitability. This model also was adapted by Spiga et al. (2010), who added morphology based on a digital reconstruction of an SPN and tested the effects of dendritic spine loss and AMPA current reduction on AP frequency during simulated upstates.

Several other complex models of dorsal striatal SPNs have been developed. A NEURON model SPN by (Gertler et al. 2008) was used to test the contribution of morphological differences between D1 and D2 SPNs in accounting for their different electrophysiological characteristics. This model was adapted (Plotkin et al. 2011) to test the ability of distal dendrites to evoke sustained somatic depolarizations. A similar model, by the

same group (Day et al. 2008), was used to investigate attenuation of the action potential as it back-propagated into SPN dendrites. Another NEURON model SPN by (Flores-Barrera et al. 2009) was used to test whether GABAergic input, which is depolarizing below its reversal potential (roughly -60 mV), plays a role in maintaining

the depolarization of an SPN during a cortico-striatal upstate. Additionally, a NEURON model with calcium dynamics including calcium release from internal stores was used to investigate the effects of synaptic inputs and back-propagating action potentials on spine calcium (Nakano et al. 2013). Most electrical models do not incorporate

significant intracellular biochemical signaling; however one SPN modeled in NEURON was coupled to a biochemical signaling model in dendritic spines to create a multiscale model (Mattioni and Le Novère 2013).

Several iterations of a dorsal striatal SPN model (Evans et al. 2012) using the GENESIS simulation software have been developed. Evans et al. (2012) investigated whether the NMDA receptor subtypes, based on the four GluN2 subunits, differentially affect the calcium influx into spines during closely timed pairings of pre- and postsynaptic activity (spike-timing-dependent plasticity protocols). Evans et al. (2013) incorporated more sophisticated calcium dynamics in dendrites to investigate the effect of action potential timing during an upstate, finding that earlier action potentials induce higher calcium influx due to calcium-dependent inactivation of calcium channels. A network implementation of this model, together with an FSI model, has been developed to investigate the effects of dopamine depletion on striatal network synchrony (Damodaran et al. 2014; Damodaran et al. 2015). The most recent iterations of this model incorporated sophisticated spine calcium dynamics and a calcium plasticity rule to successfully predict spike-timing-dependent plasticity outcomes from several experimental studies (Jędrzejewska-Szmek et al. 2017) and show that spine calcium encodes patterns of synaptic inputs with spatial specificity (Dorman et al. 2018).

An SPN model with realistic morphology was recently used to investigate the effects of clustered synaptic inputs on input/output firing properties, showing that clustered inputs which could evoke a dendritic plateau potential facilitated spiking in response to additional dispersed inputs and that distal dendritic inhibition could attenuate the plateau potential and its effect on firing (Du et al. 2017). This model was adapted (Lindroos et al. 2018) to investigate dopaminergic modulation of D1 SPNs.

Interneuron Models

Most striatal models focus on the spiny projection neurons, but there are several models of striatal interneurons.

The first complete model of a fast-spiking interneuron (FSI) (Kotaleski et al. 2006) replicated the observed spike latency and high firing frequency of striatal FSIs. This model was used to investigate how upstate firing of FSIs is controlled by transient potassium currents and the contribution of these channels to enhancing signal-to-noise ratio. This model was further used to construct a network model (Hjorth et al. 2009) that investigated the contribution of gap junctions in FSI sensitivity to coincident input from the cortex.

Several simple models of acetylcholinergic neurons (Ach) have been developed. The goal of most of these models is to explain mechanisms underlying the rhythmic firing and burst firing observed in these neurons. Two models demonstrate that two alternative mechanisms can explain membrane potential. The first model (Wilson 2005) demonstrates that Kir, HCN (hyperpolarization-activated and cyclic nucleotide-gated channel), and leak conductance in a single compartment could explain membrane potential oscillations in the voltage range of -80 to -60 mV. A second model shows that a calcium current plus calcium-dependent potassium current produces oscillations, though with a slower time course (Wilson and Goldberg 2006). Simulations further demonstrated how the slow afterhyperpolarization (sAHP) is activated by long depolarizations (even of small amplitude) but not activated by brief ones. Another model of ACh neurons (Goldberg et al. 2009) was used to investigate the role of calcium channel colocalization in mediating slow and fast afterhyperpolarizations. This model had a single electrical compartment that was subdivided into multiple concentric calcium compartments coupled by diffusion. Several calcium-binding proteins enabled the model to demonstrate that the transient calcium influx produced by an action potential preferentially binds to SK channels, whereas the lower but more prolonged calcium influx produced by subthreshold depolarization preferentially binds to the slower, higher-affinity binding proteins.

To date, there is a lack of models of other striatal interneuron types. However, a recent simple LTSI model has been published that utilizes a single compartment and reduced channels to

analyze the source of subthreshold membrane oscillations (Song et al. 2016). This model suggests that calcium-activated chloride channels may be important to regulating membrane potential oscillations in LTSIs.

Conclusion

There are several models of striatal neurons that contain cellular detail. These models vary in complexity, morphology, and active channels. Each model is configured to test a specific aspect of striatal physiology as efficiently and accurately as possible, and therefore both the simple and the complex models are valuable. With the increasing power of computers and tools for parameter optimization, the accuracy and complexity of models is likely to increase.

Basal Ganglia: Subthalamic Nucleus Cellular Models

Charles Wilson¹ and Michael Farries²

¹Department of Biology, University of Texas at San Antonio, San Antonio, TX, USA

²Department of Neurology, University of California San Francisco, San Francisco, CA, USA

Definition

The subthalamic nucleus is a key basal ganglia structure providing an excitatory innervation to the globus pallidus and substantia nigra. The

spontaneous activity of these neurons is sustained by an autonomous oscillation and interacts with ongoing activity in the external segment of the globus pallidus, with which it has reciprocal connections.

Detailed Description

Why Build a Model of Neurons in the Subthalamic Nucleus?

Interest in models of subthalamic nucleus (STN) neurons is driven by the need to understand pathological oscillations in the basal ganglia seen in Parkinson's disease and in animal models of the disease (e.g., Bergman et al. 1994) and in the therapeutic mechanism of subthalamic deep brain stimulation. The low-frequency oscillations characteristic of subthalamic cell firing in the disease are not expressed in isolated neurons and so are thought to arise from a network mechanism (e.g., Wilson 2014). A likely mechanism is offered by the reciprocal connections between the subthalamic nucleus and the globus pallidus. The STN consists of glutamatergic neurons that excite GABAergic neurons in the GPe. These in turn inhibit the STN.

The Gillies et al. (2002) mean field model indicated that oscillations in the STN- > GPe circuit could arise if the STN were powerfully self-excitatory, but experimental evidence for this was lacking (Kita et al. 1983; Sato et al. 2000). The recognition that STN neurons are intrinsic oscillators (Bevan and Wilson 1999) revived the possibility of STN-GPe oscillations without excitatory coupling between STN cells. An STN of independent oscillators would be self-exciting, but without lateral interactions the cells would not synchronize, and oscillations in the correct frequency range might not occur. Synchronization of STN cells might occur disynaptically through interactions with the GPe. A simulation of the mechanism by which the sparse connections between STN and GPe could produce synchronization requires models at the neuron level rather than mean field models.

Many models of this kind have employed generic neuron models not designed to

specifically represent the cell type-specific dynamics of the subthalamic neurons. Such models are based on the hypothesis that network activity depends only on the connectivity of the network, not the functional properties of the neurons. Some networks have been built using more faithful representations of the cells involved, using one small group of subthalamic cell models.

The Terman et al. Model

Terman et al. (2002) developed conductance-based point models of the STN cell and the GPe cell as components of a model of the pallido-subthalamic network. These included features that duplicated the cells' firing patterns as they were known at that time. The relevant components of the subthalamic cell model were autonomous single-spiking and a powerful post-hyperpolarization rebound, both of which had been emphasized in recent studies of cells in slices (Bevan and Wilson 1999; Beurrier et al. 1999). The model subthalamic neuron was validated by showing qualitative similarity to the slice data, specifically autonomous firing in the appropriate range of rates and a powerful brief depolarization and burst after termination of a hyperpolarizing current injection.

Firing Pattern

Autonomous firing was generated by a persistent sodium current. This was implemented using a strong window current at subthreshold membrane potentials as suggested by Bevan and Wilson (1999). Later work is inconsistent with this mechanism (Do and Bean 2003), but this difference makes little difference for firing properties. The simplifications of action potential repolarization and after-hyperpolarization (AHP) currents were more sweeping, employing a single non-inactivating K^+ channel adjusted to activate and deactivate very slowly in the subthreshold range. A Ca-dependent K^+ current was present but contributed little to the single-spike AHP. It was de-emphasized because STN cells show little spike-frequency adaptation during brief

episodes of high-frequency firing, rather increasing their firing over the first 100–200 ms (Hallworth et al. 2003; Wilson et al. 2004). Calcium removal was slow so that Ca-dependent K^+ current was strongly accumulating and produced a long-lasting AHP after periods of high-frequency firing. Subsequent studies of the AHP currents of STN cells suggest substantially different mechanisms governing firing rate. The fast repolarizing K^+ current deactivates rapidly, and its AHP component is brief. It also depresses during high-frequency firing (Teagarden et al. 2008). Most of the AHP is caused by SK-type Ca-dependent K^+ current. This current does not accumulate during high-frequency firing but produces a 10–30 ms AHP current following every action potential. Slow spike-frequency adaptation in STN neurons results from inactivation of persistent Na^+ current (with time constant ~ 5 s) and the accumulation of a very slow voltage-sensitive K^+ current (with time constant ~ 20 s) (Barraza et al. 2009), and the latter creates the slow AHP current seen after firing at high rates. Spike frequency adaptation is not included in any of the commonly used models.

Rebound

Two rebound currents contribute to the low threshold spike (LTS) that follows strong hyperpolarizations. The faster one is carried by calcium and caused by t-type calcium channels (Hallworth et al. 2003). Longer hyperpolarizations engage HCN currents and induce a more prolonged depolarization. In the STN cell model, these two currents were combined into a single mechanism. Post-inhibitory rebound was thought to be critical to the oscillations in STN-GPe co-cultures (Plenz and Kitai 1999). Experimental attempts to verify the presence of rebounds after synaptic inhibition have been unimpressive. Rebounds in STN neurons require hyperpolarizations lasting much longer than typical for GABA_A IPSPs (Bevan et al. 2002). On the other hand, rebound excitation in STN cells often lasts longer than in the model cell because L- and N-type calcium channels are activated by the LTS. High voltage-activated calcium

channels were included in the model but did not act to prolong rebound firing.

Effective Time Constant

In the model STN cell, slope conductance is high throughout the interspike interval. When the membrane potential is not changing rapidly, it is because strong currents are balanced. Large synaptic currents are required to change the membrane potential, and it then changes rapidly. The charge deposited by synaptic currents dissipates rapidly. This enhances the response to rapid fluctuations in synaptic current and precise timing of inhibition from the GPe. In contrast, the STN cell's I–V curve is nearly flat over most of the voltages visited during the interspike interval (Farries et al. 2010). The rise time of synaptic potentials is slow, and the charge placed on the cell by subthreshold synaptic inputs is retained and alters the membrane potential trajectory and timing of action potentials tens of milliseconds later (Fig. 1).

It is unknown whether any of these differences between the Terman et al. model and the real STN neuron are important in generating oscillatory activity in the STN–GPe network or, if they are, what kind of difference they would make. The list of ionic mechanisms that could be included in a neuron model increases with every new experimental study, and no cellular model simple enough to be used in a network model can be expected to incorporate every known cellular feature. Nobody knows which features are essential, and as always that complicates model design.

The Terman et al. model has been widely used in a variety of influential network models of Parkinson's disease and its treatments, including deep brain stimulation (e.g., Guo et al. 2008).

Otsuka Model and Plateau Potentials

Studies of STN neurons have described plateau potentials following applied current pulses or post-inhibitory rebound (Nakanishi et al. 1987; Beurrier et al. 1999), which depend on voltage-activated Ca^{2+} currents. A one-compartment conductance-

based model STN cell incorporating these Ca^{2+} currents and capable of plateau potentials was presented by Otsuka et al. (2004). This was not a comprehensive model but demonstrated that Ca^{2+} currents measured in voltage clamp possessed properties necessary for plateau potentials as in intracellular recordings. The features of the Otsuka model should be incorporated into any comprehensive model of the STN neuron. However, not all STN cells show plateau potentials, so their inclusion in STN models must be accompanied by some treatment of heterogeneity. The Otsuka et al. model has been used as is or with slight modifications in several basal ganglia network models (e.g., Shouno et al. 2017).

Gillies and Willshaw Model

Models of STN neurons have rarely included dendrites or an axon. One exception is the model by Gillies and Willshaw (2006). This model contains a simplified but still complex dendritic tree, separate fast and persistent Na^{+} currents, fast repolarization current, and realistic Ca^{2+} and Ca -dependent K^{+} currents. Many of its channel properties are based on measurements from other neurons, and the distribution of channels on the dendrites is largely speculative, but it reproduces several of the neurophysiological properties of STN neurons, including long rebounds, plateau potentials, and rhythmic bursting during hyperpolarization. Execution of this model is more computationally intensive than the others, and it has not been extensively used in models of STN- > GPe interactions.

Farries and Wilson Model

Neuron models for networks are not expected to be quantitatively accurate. It is usually considered enough for the neuron representation to share some single property with its real-life counterpart—for example, steady-state gain or time constant of adaptation. The cellular property chosen for validation of the model reflects the network designer's interpretation of what constitutes the essential computational features of the cell in its network. Farries

Basal Ganglia: Subthalamic Nucleus Cellular Models, Fig. 1 (continued)

and Wilson (2012) constructed a simple model of the STN cell intended to reproduce its spontaneous activity and phase resetting curve. The phase resetting curve describes the changes in interspike intervals produced by one or more small synaptic currents occurring in the interspike interval during repetitive firing. This model was motivated by the observations that subthalamic neurons are autonomous pacemakers and receive many small synaptic inputs from cells that also have ongoing background firing. This model did not include the response to deep hyperpolarizations, as it omitted rebound currents, which are not engaged by the kind of stimuli used to generate phase resetting curve. This may not be a critical omission, as rebounds are probably rarely engaged during ongoing synaptic activity (Bevan et al. 2002). The model implemented more accurate repolarizing and AHP currents, and its I–V curve was adjusted to match that of the STN cell. Slope conductance was low during most of the interspike interval, and synaptic inputs arriving during most of the interspike interval produced changes in the timing of the next spike, like those observed in STN neurons. The model was used to derive the phase resetting curve from the shape of the I–V curve and the AHP conductance (Fig. 1).

Phase Model

Phase-resetting curves are readily measured in experiments and can be used to predict the responses of the same neuron to arbitrary patterns of synaptic input. The neuron's response is calculated using a phase model, characterized by only a baseline firing rate, an input current, and a phase resetting curve. The validity of the model's prediction is not guaranteed, because the model assumes that the cell's state does not stray far from its unperturbed closed path in parameter space. For this reason, the use of phase models has usually been restricted to models of weakly connected networks, in which cells continue to fire rhythmically. Wilson et al. (2014) tested the accuracy of the phase model for STN neurons subjected to dense noise stimuli, which strongly disrupted rhythmic firing (Fig. 2). The model provided an accurate quantitative prediction of the statistics of firing (e.g., coefficient of variation). A phase model based on the experimentally measured phase resetting curve of each cell accurately predicted the individual interspike intervals from the same cell during application of arbitrary patterns of current noise.

Basal Ganglia: Subthalamic Nucleus Cellular Models,

Fig. 1 (a) Response of two STN models and an example STN neuron to an EPSP. The reversal potential of the models' leak conductance was adjusted to produce autonomous ISIs of 160 ms, matching the unstimulated ISI of the recorded STN neuron (*black traces*). The EPSC was simulated as a product of exponentials ($\tau_{\text{rise}} = 0.8$ ms, $\tau_{\text{decay}} = 1.5$ ms), and EPSC amplitude was adjusted for each model to produce a peak depolarization of 4 mV, matching the recorded neuron's EPSP (*red traces*). The real STN neuron was recorded in a rat brain slice in the presence of GABA receptor antagonists. (b) Phase shift (advance in spike time caused by an EPSP divided by the duration of the autonomous ISI) as a function of EPSP size for EPSPs delivered halfway through the autonomous ISI (i.e., same time as in *A*, at a phase of 0.5). Because the EPSPs arrived at a phase of 0.5, the maximum possible phase shift (corresponding to a spike triggered immediately by the EPSP) was 0.5. The *red circles* plot average phase shift in recorded STN neurons for EPSPs arriving at phases of 0.45–0.55 against average EPSP size; each circle

is from a different neuron. The *red line* is a linear regression on these data ($r^2 = 0.71$, fit slope = 0.05 of phase shift per mV EPSP, $p < 0.0001$, $n = 89$). For the Terman et al. (2002) model, "EPSP size" is EPSC amplitude multiplied by 0.6 mV per unit current density, allowing the graph to include synaptic strengths that trigger spikes at short latency. This conversion factor is derived from the measured 4 mV EPSP shown in *A*. (c) Infinitesimal phase response curves (iPRCs) for two STN models and an example STN neuron (same cell as in *A*). The iPRC gives the phase shift (normalized change in spike time) caused by a stimulus per unit stimulus strength (EPSP size, in this case) in the limit of very weak stimuli. This measure of sensitivity to input (phase shift per mV EPSP) varies as a function of when during the autonomous ISI (stimulus phase) the input is delivered. For real STN neurons and the Farries and Wilson (2012) model, this sensitivity to very small inputs is a good predictor of the response to much larger inputs, as illustrated in *B* by the near-linear relationship between stimulus size and response magnitude

Basal Ganglia: Subthalamic Nucleus Cellular Models, Fig. 2 Example activity from an STN cell in the absence (a) and presence (b) of dense current noise (c). In the presence of the noise stimulus, repetitive firing is greatly disrupted, as indicated by the change in interspike interval distribution, as shown by comparison of d (without noise) and

e (with noise). (f) Measured phase resetting curve for the same cell. A phase model using the interpolated phase resetting curve was integrated starting at each spike time to predict the interspike intervals. The predicted intervals are indicated using red dots in b. (g) Comparison of predicted and actual interspike intervals. The red line in g indicates identity

Summary

The diversity of STN neuron models reflects the diversity of goals set by model designers. STN neurons have complex dynamics that deviate greatly from models of the integrate-and-fire family. Many more accurate models focused on reproducing plateau potentials or post-hyperpolarization rebound, but these features may not be prominent during normal firing. For models to be used in networks, it is most desirable for the model to accurately reproduce the STN neurons' autonomous firing and dynamic response to changing synaptic input.

Bayesian Estimation

► Estimation of Neuronal Firing Rate

Bayesian Inference with Spiking Neurons

Sophie Deneve

Group for Neural Theory, École Normale Supérieure Paris, Paris, France

Definition

Neurons respond reliably to external stimuli despite the fact that their input is noisy and the state of the environment changes constantly (e.g., stimuli appear or disappear unpredictably). The Bayesian spiking neuron (BSN) framework interprets neural dynamics as a form of probabilistic inference and describes how neurons and neural circuits should be optimally tuned to the temporal statistics of their inputs and the level of noise. Output spike trains communicate probability distributions over stimulus states to downstream neurons using a predictive coding strategy.

Detailed Description

General Framework

In BSN formalism, prior assumptions about the input tuning curves, noise, and temporal dynamics of the stimulus are treated as the parameters of an internal predictive model (Lochmann and Deneve 2011). Such an internal model represents how the “hidden” stimulus state causes the “observed” noisy inputs. These assumptions are in turn reflected in the structure and dynamics of a corresponding neural network. For example, the presence or absence of an external sensory stimulus can be represented as a binary “hidden” variable modulating the input rates. Such internal model can be implemented in a single spiking neuron (Fig. 1a, Deneve 2008a).

In turn, the parameters of the internal model fully predict the biophysical properties of the spiking neurons, e.g., synaptic time constants, adaptation, synaptic weights, and ring dynamics.

Since these parameters also reflect the “natural” (i.e., expected) statistics of the synaptic inputs, these optimal biophysical parameters can be learned in an unsupervised way (through spike-time-dependent plasticity rules) (Deneve 2008b; Mongillo and Deneve 2008).

Dynamics of Bayesian Spiking Neurons

BSNs are similar to adaptive “integrate-and-re” neurons and are described by two dynamic equations, one corresponding to synaptic integration of inputs (inference) and the other to a dynamic neural threshold dependent on recent spike history (encoding).

Inference consists of computing the probability distribution over the stimulus state x_t , given the feed-forward synaptic inputs received so far, $s_{0 \rightarrow t}$. This can be expressed in terms of the log posterior probability, $L(x, t) = \log(p(x_t | s_{0 \rightarrow t}))$. Using simplifying assumptions such as (1) Poisson distributed input spike trains and (2) Markovian dynamics for stimulus x_t (i.e., x_t only depends on x_{t-dt}), this equation takes the general form:

$$\frac{\partial L(x, t)}{\partial t} = -\phi(L(x, t)) + \sum_i w_i(x) s_i(t) \quad (1)$$

where $s_i(t)$ is an input spike train while the “synaptic weights” $w_i(x)$ depend on the input tuning curves. ϕ is a (typically nonlinear) “leak” term dependent on the dynamics of the hidden variable (e.g., how quickly the stimulus changes). This equation can correspond to synaptic integration in single neuron (for binary x_t) or in a recurrent neural network (for multinomial or continuous x_t , as in Fig. 1b).

Encoding consists of representing an estimate $\hat{L}(x, t)$ of the log posterior in the output spike trains. In order to do this, the BSN uses a “greedy” predictive coding scheme, i.e., neurons reset whenever their membrane potential, defined as the prediction error $V_j(t) = k_j * (L - \hat{L})$ (where k_j is a kernel specific to each neuron), exceeds a particular threshold. As a result, each new spike decreases the coding (prediction) error $L(x, t) - \hat{L}(x, t)$. With respect to self-consistency, $\hat{L}(x, t)$ is

Bayesian Inference with Spiking Neurons, Fig. 1 Examples of internal predictive models and their BSN implementations. (a) Case of single binary stimulus (dashed circle), modulating two input ring rates (dashed arrows and line), generates two input spike trains (vertical lines). A single spiking neuron (yellow star) receiving these convergent synaptic inputs (plain connections) can represent the log probability of stimulus present in its output spikes, using predictive coding (thin plain arrow).

(b) Case of a single continuous variable evolving with Markovian “Brownian motion.” In this case, the log posterior is represented by a population of neurons whose spike trains (colored vertical lines) track the stimulus. Predictive coding requires lateral inhibitory connections (thin arrows). (c) Case of 3 different binary stimuli co-modulating the synaptic inputs. Explaining away requires divisive presynaptic inhibition between neurons (dashed connections)

assumed to be the result of postsynaptic integration of the output spike trains in downstream neurons, e.g.,

$$\tau \frac{\partial \hat{L}(x, t)}{\partial t} = -\hat{L}(x, t) + \sum_i k_j(x) o_j(t) \quad (2)$$

The result can be interpreted as a recurrent network of adaptive leaky integrate-and-re neurons with lateral connections $k_i * k_j$ (Fig. 2b). By always maintaining a small prediction error, BSNs represent the posterior probability efficiently (Fig. 2a).

Extension to Multiple Stimuli

The framework can be extended to the tracking of more than one stimulus at a time (Fig. 1c). This is particularly relevant for the processing of sensory scenes, since the same sensory inputs can usually be explained by different combinations of overlapping features. For example, different speech sounds activate highly overlapping sets of auditory receptors. The auditory input is explained by

either one or the other phoneme, but not both. Thus, neurons selective to similar phonemes (e.g., “ba” and “da”) will need to compete: if they did not, neurons would have highly correlated, nonselective responses. This phenomenon is called “explaining away.”

Let us assume that the sensory input is caused by K different stimuli $x_k(t)$ combining linearly to cause the sensory scene, i.e., each input $s_i(t)$ is a Poisson process with instantaneous firing rate $f_i(t) = \sum_k w_{ik} x_k(t)$. In a BSN implementation of this internal model, the *encoding* is identical, but the *inference* needs to implement explaining away. The network equations are as same before, except that the synaptic weights are no longer fixed (as in Eq. 1), but divisively gain modulated by the context. More precisely, the effective weights $\tilde{w}_{ij}(t)$ between input i and feature detector k are given by

$$\tilde{w}_{ik}(t) = \frac{w_{ik}}{1 + \sum_{j \neq k} w_{ij} \hat{x}_j(t)} \quad (3)$$

where $\hat{x}_j(t)$ is the prediction (i.e., the expected value) of feature j at time t . This can be

Bayesian Inference with Spiking Neurons, Fig. 2 Predictive coding and implication for contextual modulation of receptive fields. **(a)** The log probability of stimulus, $L_t = L(x, t)$, is tracked over time by an output estimate $\hat{L}_t$ corresponding to a leaky integration of the output spike train. **(b)** This can be implemented by an adaptive integrate-and-re neuron whose membrane potential is a function of the prediction error $L_t - \hat{L}_t$. **(c)** When

multiple overlapping “blob-shaped” stimuli are represented (*dashed grey line*), the receptive field of the corresponding neuron is highly dependent on context. For example, it is narrow and center surround for high-contrast stimuli (*plain red*), wide and without surround for low-contrast stimuli (*dot-dashed blue*), and repulsed in the presence of a stimulus in the left surround (*dashed green*)

implemented by lateral divisive inhibition in a recurrent neural network (Fig. 1c). Each input to each neuron is presynaptically shunted according to how well this input is predicted by other neurons.

Some Applications of the BSN Framework

One of the most important implications of the BSN framework is that the “Poisson-like” variability observed in cortical spike trains is a natural consequence of predictive coding. It reflects sensory noise and redundancy between neurons (e.g., many neurons have similar coding kernels), but *not* neural noise. The variability persists even when the inputs are not Poisson distributed and even when the input is completely deterministic (Bourdoukan et al. 2012).

Moreover, this framework assumes highly dynamical and adaptive response properties. BSNs provide “ideal observer” models of single neurons or microcircuit and thus are useful tools to relate neural spike trains with their hypothetical functions. While those models are highly testable (and disprovable), they largely remain to be tested experimentally.

More specifically, BSNs have been shown to achieve quasi-optimal information transmission in single neurons (Lochmann and Deneve 2008).

Populations of BSN neurons can represent slowly varying variables (such as position or direction of motion) and implement optimal working memories (Boerlin and Deneve 2011). Finally, BSNs representing overlapping stimuli can account for a large number of contextual modulation of sensory responses, such as divisive normalization, adaptation, surround suppression, and repulsion, as illustrated in Fig. 2c (Lochmann and Deneve 2011).

Relation to Other Approaches

In addition to the BSN, several other frameworks have proposed different encoding of uncertainty with spikes. For example, sampling models interpret spikes as samples from the posterior probability distribution (rather than a deterministic representation of the log posterior) (Berkès et al. 2011; Buesing et al. 2011). The “probabilistic population coding” (PPC) approach represents log-posteriors in the output firing rates. This can be implemented in a spiking network using random spike generators or large balanced spiking networks (Beck et al. 2008), the underlying assumption being that the added noise is neglectable compared to the uncertainty already present in the input.

Behavioural Analysis, Bayesian

Samuel J. Gershman

Definition

Bayesian analysis is a method for reasoning probabilistically about parameters of a model given some observed data. Applied to behavioral data, Bayesian analysis can be used to fit and compare models of cognition. This approach to behavioral data analysis offers a number of advantages over classical (frequentist) analysis, including a coherent representation of uncertainty, flexibility to handle complex models and missing data, and an avoidance of pathologies inherent to significance testing based on p -values.

Detailed Description

Bayesian analysis starts with the specification of a joint distribution on the data D and parameters (or hidden variables) H . This joint distribution can be broken down into two components: $P(D, H) = P(D|H) P(H)$. The first component, $P(D|H)$, is known as the *likelihood*, and the second component, $P(H)$, is known as the *prior*. Given some data, we are interested in

the conditional distribution, $P(H|D)$, commonly known as the *posterior*; this distribution specifies everything we know about H given the observed data and our prior beliefs. Bayes' rule stipulates how to form the posterior from the prior and likelihood:

$$P(H|D) = \frac{P(D|H)P(H)}{\sum_R P(D|H)P(H)}$$

The denominator is sometimes known as the *marginal likelihood*. When H is continuous, the summation is replaced by integration. A practical overview of Bayesian analysis can be found in Kruschke (2010). Below we discuss some of the relevant issues that arise in applying Bayesian analysis to behavioral data.

Posterior Probabilities Versus P -values

The classical approach to behavioral data analysis is based on the null hypothesis significance testing (NHST) framework, in which the significance of a summary statistic is evaluated by calculating the probability of obtaining an equally or more extreme value if the statistic was drawn from a null distribution. If the resulting p -value is below some conventional threshold (e.g., 0.05), the null hypothesis is rejected and the result is considered significant. This framework is related to Bayesian analysis: the p -value is the tail probability of the likelihood when H corresponds to the null hypothesis.

In contrast to p -values, posterior probabilities quantify the evidential support for all possible values of H . Often different values of H can plausibly have generated the data, and the posterior captures this uncertainty. In contrast, the confidence intervals of NHST express the range of H that would not be rejected by a significance test.

Under NHST, when multiple tests are applied to a data set, the probability of erroneously declaring a null effect significant increases. This necessitates some kind of correction for multiple comparisons. Bayesian analysis does not require such corrections, since there is a single posterior

distribution that does not depend on how many ways you examine it.

Hierarchical Models

A powerful use of Bayesian analysis is the construction of hierarchical models in which uncertainty about the parameters of the prior is captured by placing a “hyper-prior” on these parameters (Lee 2011). An important example of this is modeling individual differences: each subject in a study has a separate set of parameters, but these parameters are coupled by virtue of being drawn from a common group-level distribution. One advantage of hierarchical models is that they allow sharing of “statistical strength” between subjects, such that the parameter estimates of one subject are informative about the parameter estimates of another subject. At the same time, subjects are allowed to express idiosyncratic parameters. Hierarchical models can thus strike a balance between forcing all subjects to have the same parameters and modeling each subject separately.

Model Comparison

An important problem in cognitive modeling is model comparison. The Bayesian approach to this problem centers on calculating the *Bayes factor* (Kass and Raftery 1995), which is the ratio of marginal likelihoods for two models. The Bayes factor rewards models that fit the data better but penalizes model complexity. Intuitively, complex models are able to fit a given data set better than simple models, but complex models also spread their probability mass over many data sets, and consequently the probability of any given data set will tend to be smaller.

Whereas the posterior will often be relatively insensitive to the prior when the amount of data is large, Bayes factors can be exquisitely sensitive to the choice of prior (Kass and Raftery 1995). This has sometimes been considered a drawback of Bayesian model comparison. However, others

(e.g., Vanpaemel 2010) have argued that prior sensitivity is reasonable, since the prior should be considered part of a fully specified cognitive model.

Computation

For all but a small class of models, employing Bayes' rule exactly is computationally intractable. This happens because the marginal likelihood computation involves summing over all possible hypotheses, which is infeasible for large hypothesis spaces. Consequently, most algorithms for Bayesian analysis use approximations. Most commonly, these algorithms approximate the posterior with a set of stochastic samples – the so-called *Monte Carlo* approximations (Robert and Casella 2004). As the number of samples increases, the approximation becomes increasingly accurate. There are several software packages that compute Monte Carlo approximations automatically given a probabilistic model (see Kruschke 2010 for an introduction), making Bayesian methods widely accessible for behavioral data analysis.

Bifurcation Analysis

William Barnett and Gennady Cymbalyuk
The Neuroscience Institute, Georgia State
University, Atlanta, GA, USA

Definition

Bifurcation analysis provides theoretical guidelines and a powerful analytical framework to tune the activity of neuronal models. A bifurcation is a qualitative change in the activity of a dynamical system, such as a transition from silence to spiking. Bifurcation analysis identifies general dynamical laws governing transitions between activity regimes in response to changes in controlling parameters. By using these quantitative laws, the temporal characteristics of a neuronal model can be tuned to reproduce the characteristics of experimentally recorded activity by navigating the parameter space in the vicinity of bifurcations. In most of the bifurcations described here, the general shape of the waveform – for example, the shape of action potentials in a time series – is preserved, while a specific temporal characteristic changes.

Detailed Description

The knowledge of the bifurcations of a model neuron provides quantitative laws governing the temporal characteristics of spiking activities. Neurons can be envisaged as nonlinear dynamical systems. Bifurcation analysis has been applied to the study of spiking, bursting, and chaotic neuronal systems (Rinzel 1987; Guckenheimer et al. 1993, 1997; Rinzel and Ermentrout 1998; Ermentrout and Terman 2010; Ghigliazza and Holmes 2004; Rabinovich et al. 2008). Biophysical parameters are used as controlling parameters, and changes in regimes of activity can be identified concomitantly with bifurcations (Rinzel 1978; Guckenheimer et al. 1993, 1997; Shilnikov and Cymbalyuk 2005; Shilnikov et al. 2005; Medvedev 2006; Barnett

Bifurcation Analysis, Table 1 Dynamical laws arising from specific bifurcations. The bifurcation parameter α takes its critical value for bifurcation at α^*

Bifurcation	Dependence
Homoclinic	Period $\propto -\ln(\alpha - \alpha^*)$
SNIC	Period $\propto 1/\sqrt{ \alpha - \alpha^* }$
Blue Sky catastrophe	Period $\propto 1/\sqrt{ \alpha - \alpha^* }$
Andronov-Hopf	Amplitude $\propto \sqrt{ \alpha - \alpha^* }$

and Cymbalyuk 2014). The association of transitions between regimes of neuronal activity with specific bifurcations gives predictions about the properties of stationary and oscillatory solutions (Booth et al. 1997; Doiron et al. 2003; Shilnikov and Cymbalyuk 2005; Shilnikov et al. 2005; Barnett and Cymbalyuk 2014). This approach is applicable for tuning the dynamics of neuronal activity – such as bursting, spiking, and rest states – with biophysical parameters. We provide examples of four bifurcations that determine quantitative characteristics of activity: the homoclinic bifurcation, the saddle-node bifurcation on an invariant circle (for bursting and for tonic spiking), the blue sky catastrophe, and the Andronov-Hopf bifurcation (Table 1). We present the dynamical laws generated by these bifurcations in the context of spiking, bursting, and transient activity.

Spiking

Three bifurcations of closed periodic orbits are ubiquitously implicated in the control of spiking activity. A saddle-node bifurcation on invariant circle (SNIC) and a homoclinic bifurcation describe how the frequency of spiking depends on a controlling parameter α , e.g., the injected current. A supercritical Andronov-Hopf bifurcation describes the dependence of the amplitude of oscillations on the bifurcation parameter.

A SNIC occurs when an equilibrium possessing the properties of both a saddle and a node – a saddle-node equilibrium – is born on a closed periodic orbit and the eigenvectors

associated with the half-stable direction of the saddle-node equilibrium are tangent to the periodic orbit. This bifurcation describes the transition of spiking into silence (Gutkin and Ermentrout 1998). At the critical value for bifurcation, α^* , the saddle-node equilibrium obstructs the spiking orbit. For values of α that support spiking and are close to α^* , the frequency of spiking activity is proportional to $\sqrt{|\alpha - \alpha^*|}$. This bifurcation does not constrain the amplitude of spiking. This scenario is an example of the type I spiking scenario (Gutkin and Ermentrout 1998; Izhikevich 2007).

A homoclinic bifurcation of a saddle equilibrium can terminate a spiking regime (Izhikevich 2007). It occurs when an orbit is interrupted by the saddle; as α changes and approaches the critical value for bifurcation, α^* , the spiking frequency decays according to $-1/\ln(|\alpha - \alpha^*|)$.

In a supercritical Andronov-Hopf bifurcation, a stable focus loses stability, and a stable periodic orbit with zero amplitude and nonzero frequency is born. The frequency is inherited from the resonant frequency of the focus. In subthreshold oscillations or spiking activity associated with this bifurcation, the amplitude of the orbit grows proportionally to $\sqrt{|\alpha - \alpha^*|}$. This scenario is an example of the type II spiking scenario (Gutkin and Ermentrout 1998; Izhikevich 2007; Rinzel and Ermentrout 1998).

Bursting

Four types of bifurcations are crucial for the control of temporal characteristics in bursting activity: the SNIC for bursting, the blue sky catastrophe, the cornerstone bifurcation, and the Lukyanov-Shilnikov bifurcation.

In bursting activity, the SNIC describes the transition from bursting to silence (Booth et al. 1997; Doiron et al. 2003; Barnett and Cymbalyuk 2014). According to this bifurcation, the interburst interval grows smoothly and is proportional to $1/\sqrt{|\alpha - \alpha^*|}$ as the bifurcation parameter, α , approaches the critical value α^* (Fig. 1). At the bifurcation, a saddle-node equilibrium is born on the bursting orbit.

Bifurcation Analysis, Fig. 1 The transition from bursting to silence and the transition from bursting to tonic spiking. (a) Initial values for α and β produce periodic bursting activity. (b, c) The parameter α is varied to approach its critical value for bifurcation, α^* , and the interburst interval increases. (f) Curve fits for the interburst interval took the form $b/\sqrt{|\alpha - \alpha^*|} + c$. (d, e)

The parameter β is varied to approach its critical value for bifurcation, β^* , and the burst duration increases. (g) Curve fits for the burst duration took the form $b/\sqrt{|\beta - \beta^*|} + c$. (f, g) Graphs are plotted in the log-log scale. The interburst interval and burst duration are depicted as blue dots. The curves fitted to these data are depicted as red curves

The blue sky catastrophe occurs when a saddle-node periodic orbit is born on the manifold that governs spiking in a bursting neuron

(Shilnikov and Cymbalyuk 2005; Barnett and Cymbalyuk 2014). This bifurcation describes the transition from bursting to tonic spiking. The

Bifurcation Analysis, Fig. 2 The inverse-square-root laws in transient responses triggered by a pulse of current for parameter values that support silent and tonic spiking regimes. (a–d) An individual burst was triggered by a hyperpolarizing pulse of injected current. Burst duration was controlled by the voltage of half activation of a potassium current (α). The duration of individual bursts were (a) 10.3 s, (b) 103.5 s, and (c) 309.3 s for different values of α . (d) The log-log graph of burst duration of individual bursts plotted against the difference between the voltage of half activation of a potassium current and its critical value for bifurcation (α^*). The blue dots correspond to the burst duration measured

at the respective values of α . The red curve is the graph of the curve fitted in the form $b/\sqrt{\alpha^* - \alpha} + c$. (e–h) Latency to spiking was shown by administering an individual pulse of injected current. Interburst interval was controlled by the half activation of a hyperpolarization-activated current (β). The delays shown here are (e) 10.3 s, (f) 103.4 s, and (g) 317.7 s for different values of β . (h) Latency to spiking for sampled parameter values (blue dots) and the graph of the curve fitted to $b/\sqrt{|\beta^* - \beta|} + c$ (red curve) were plotted in log-log scale against the sampled values of β where β^* is the critical value for bifurcation

burst duration grows smoothly and is proportional to $1/\sqrt{|\beta - \beta^*|}$ as the bifurcation parameter, β , approaches the critical value β^* (Fig. 1).

The cornerstone bifurcation satisfies the conditions of both the SNIC and the blue sky catastrophe; it is a global codimension-2 bifurcation

(Shilnikov and Turaev 2000; Barnett and Cymbalyuk 2014). This bifurcation describes the independent control of interburst interval and burst duration: one parameter, α , controls the transition from bursting to silence as in the SNIC, and another parameter, β , controls the transition from bursting to spiking as in the blue sky catastrophe. At the critical value for both parameters, (α^*, β^*) , there occurs both the saddle-node equilibrium and the saddle-node periodic orbit. In this way, the duration of the interburst interval is controlled as in the SNIC, and the burst duration is controlled as in the blue sky catastrophe (Fig. 1) (Barnett and Cymbalyuk 2014).

The Lukyanov-Shilnikov bifurcation is a homoclinic bifurcation of a periodic orbit (Lukyanov and Shilnikov 1978). In bursting, this bifurcation occurs when the unstable manifold of the saddle-orbit leads into the stable manifold of the orbit (Shilnikov et al. 2005). The unstable manifold near the saddle-orbit determines the duration of each burst. Near this bifurcation, bursting is commonly chaotic, and on average, the burst duration grows proportionally to $-\ln(|\alpha - \alpha^*|)$ as the bifurcation parameter, α , approaches the critical value α^* .

Transient Activity

Transient dynamics are critical for information processing (Rabinovich et al. 2008). The temporal characteristics of transient activity can similarly be governed by bifurcations. Typically, temporal laws are associated with global bifurcations. However, a local bifurcation can determine the timescale of transient neuronal responses to external perturbations, such as a pulse of synaptic current (Fig. 2).

The saddle-node bifurcation for periodic orbits can impose temporal laws on transient spiking activity in an endogenously silent neuron (Roa et al. 2007). For values of the bifurcation parameter α which support silence and are close to the birth of the spiking regime at α^* , the dynamics of perturbation-induced transient spiking activity are controlled by the proximity ($|\alpha - \alpha^*|$) to the bifurcation. Far from the bifurcation, a

perturbation may trigger a single action potential, but as the quantity $|\alpha - \alpha^*|$ becomes small, the same perturbation induces an increasing number of spikes. The duration of this transient activity – under the condition of an invariant external stimulus – is proportional to $1/\sqrt{|\alpha^* - \alpha|}$. A similar scenario is generated by the cornerstone bifurcation (Fig. 2) (Barnett and Cymbalyuk 2014).

In the context of the endogenously tonically spiking neurons, the cornerstone bifurcation describes a transient silent interval after inhibition according to the properties imposed by a saddle-node bifurcation for equilibria (Barnett and Cymbalyuk 2014). The return to the spiking state after inhibition is delayed if α is close in value to α^* , and this delay is proportional to $1/\sqrt{|\alpha - \alpha^*|}$ (Fig. 2).

Conclusions

We have described how the applications of bifurcation analysis to neuronal dynamics governs characteristics of oscillatory activity. In spiking activity, the homoclinic and saddle-node bifurcation on invariant circle each control spike frequency, and the Andronov-Hopf bifurcation controls spike amplitude. In bursting activity, the SNIC, the blue sky catastrophe, the cornerstone bifurcation, and the Lukyanov-Shilnikov bifurcation each impose temporal laws on the period of bursting activity. In transient dynamics, the saddle-node bifurcation for periodic orbit determines the duration of individual perturbation-evoked bursts in endogenously silent neurons, and the saddle-node bifurcation for equilibria determines the delay before spiking after inhibition in an endogenously spiking neuron. Knowledge of these laws describes mechanisms underlying modulation and adjustment of stationary and oscillatory regimes and transient responses of neurons.

Bifurcations Dynamics of Single Neurons and Small Networks

Amitabha Bose

Department of Mathematical Sciences, New Jersey Institute of Technology, Newark, NJ, USA

Definition

A bifurcation occurs when a system undergoes a qualitative change in its output as a result of a change in parameter. Under certain conditions, the voltage of a cell membrane can change from being at rest to becoming oscillatory as a result of a bifurcation. Oscillatory properties of small networks are often understood using bifurcation analysis.

Detailed Description

What Is a Bifurcation?

The word bifurcate is commonly used to denote a split, as in “up ahead, the road bifurcates into two parts.” The use of the term in this context implies that a driver traveling on this road can make a real-time choice of being able to take one or the other branch of the road when the bifurcation point is reached. In mathematics, and in its application to neuroscience, the term bifurcation has an entirely different contextual meaning. While a mathematical bifurcation is similar in that it involves different branches, the decision on which branch is chosen is largely made a priori and depends on the choice of parameters.

It is instructive to first gain some insight into situations that are not bifurcations. Different initial conditions converging to different solutions of the same differential equation while all parameters are held constant are not examples of bifurcations. Instead it may be that one initial condition lies in the basin of attraction of a particular solution, while the other one does not. Think, for example, of a double well potential where each well can trap particles starting with different initial conditions.

A solution to a differential equation that is perturbed and then suddenly veers off toward another attracting solution is also not an example of a bifurcation. In these examples, just because a change in behavior has occurred or a difference in convergence is observed, a bifurcation has not occurred. To qualify as a bifurcation, the change in behavior must be associated with a change in a parameter value.

Bifurcations arise in mathematical equations called dynamical systems. A dynamical system can generically be defined by the equation.

$$\frac{dx}{dt} = F(x, \mu). \quad (1)$$

where x is an n -dimensional vector of unknowns, μ is an m -dimensional vector of parameters, and F is a function that depends on the two. For the time being, assume that $m = 1$ and there is only one parameter of interest. Eq. 1 describes how the dependent variable x evolves in time under the flow dictated by $F(x, \mu)$. A bifurcation occurs when a system undergoes a qualitative change in its output as a result of a change in the parameter μ . A bifurcation analysis of Eq. 1 would involve systematically characterizing the different types of solution $x(t)$ that arise for different values of the parameter μ .

In general, a dynamical system can exhibit local and/or global bifurcations. Local ones are more prevalent in neuroscience and also easier to recognize and understand. The simplest local bifurcation involves assessing the existence and stability of fixed points of Eq. 1. A fixed point x^* is a value such that $F(x^*, \mu) = 0$ for either a specific value of μ or a set of values of μ . A fixed point can be asymptotically stable (all nearby initial conditions converge to it), stable (initial conditions that start nearby stay nearby it), or unstable (at least one nearby initial condition leaves a neighborhood of it). Often, and somewhat confusingly, the term stable is used in place of asymptotically stable. Both the existence and stability of a fixed point x^* can depend on the parameter μ in which case the possibility of a local bifurcation exists. To determine if one occurs, Eq. 1 is linearized about x^* and the eigenvalues

of the ensuing Jacobian matrix are analyzed. The eigenvalues also depend on the parameter μ . Different bifurcations correspond to the eigenvalues satisfying specific mathematical conditions for different values of μ . Similarly, a periodic solution of Eq. 1 can undergo a local bifurcation as a parameter is varied. As discussed later, such bifurcations can often be studied using a discrete map rather than a continuous flow. See Guckenheimer and Holmes (1983) for a detailed analysis of both local and global bifurcations.

Bifurcation analysis is a useful tool in mathematics because it simplifies the identification of different kinds of stable and unstable solutions. Each bifurcation type has a concomitant set of stable or unstable solutions that are produced (or destroyed) as a result of it. The conditions for identifying the existence of a bifurcation are often easier to satisfy than proving the existence of an actual solution. In neuroscience, bifurcations are of importance not just at the single-cell level but also in understanding the dynamics of networks. As described below, often a bifurcation mechanism that has been identified at the single-cell level suggests how dynamical changes (not necessarily bifurcations) occur at the network level.

Typical Bifurcations in the Dynamics of Single Neurons

Perhaps the most widely studied bifurcations involving single neurons are those that give rise to oscillations. Take a neuron whose voltage is at rest. The resting membrane potential represents a stable state. If after the injection of a constant amplitude current, the membrane voltage exhibits rhythmic behavior, then a bifurcation has occurred. Mathematically, there are two typical bifurcations that characterize this change in behavior. The first is called an SNIC (saddle node on an invariant circle) bifurcation and the second is a Hopf bifurcation. Both bifurcations arise in common neuronal models such as the two-dimensional Hodgkin-Huxley (Ermentrout and Kopell 1998) or Morris-Lecar (Morris and Lecar 1981) equations.

Consider a set of two equations that depend the parameter I_{ext} .

$$\begin{aligned}\frac{dv}{dt} &= f(v, w) + I_{ext} \\ \frac{dw}{dt} &= \epsilon g(v, w).\end{aligned}\quad (2)$$

In Eq. 2, the variable v represents voltage, w a recovery variable, and ϵ a positive number used to demarcate the time scales of the two variables. When ϵ is small, then Eq. 2 effectively has a fast and a slow time scale; v is called the fast variable and w the slow. The parameter I_{ext} can be thought of as an external current that only affects the membrane voltage. The v -nullcline is defined as the set of points (v, w) that satisfy the equation $f(v, w) = 0$. For the two models mentioned above, the v -nullcline is a cubic-shaped curve. The w -nullcline, the points (v, w) such that $g(v, w) = 0$, is sigmoidal-shaped like a typical activation or inactivation curve.

To understand the SNIC bifurcation, suppose that at $I_{ext} = 0$, there are two intersections of the v - and w -nullclines near the local minimum of the cubic (Fig. 1a). These intersections correspond to fixed points of Eq. 2. Linearizing at them would show that under generic assumptions, the intersection on the left branch is a stable node (attracting nearby trajectories) and the one on the middle branch is a saddle point (unstable with only one attracting direction and other directions being repelled). As I_{ext} is increased, the v -nullcline moves up in the $v - w$ phase plane and the two fixed points come closer to one another. At the SNIC bifurcation value I_{SNIC} , the fixed points coincide and become one. For $I_{ext} > I_{SNIC}$ there

are no longer any fixed points in a neighborhood of the local minimum and a periodic orbit arises. Figure 2a shows a bifurcation diagram associated with this situation. The diagram can be interpreted as follows. For each fixed value I_{ext} , the vertical slice at that value shows the steady-state solutions that exist. Solid curves denote stable solutions and dashed curves are unstable ones. For instance, when $I_{ext} = I_1$, there are three fixed points. The one with smallest voltage is stable, while the other two are unstable. At $I_{ext} = I_2$, there is an unstable fixed point and a stable periodic solution. The solid blue curves are the upper and lower boundaries of the voltage amplitude of the periodic solution. In this and subsequent figures, blue curves are associated with periodic solutions and black curves with fixed points. Oscillations that arise through an SNIC bifurcation can have arbitrarily low frequencies and typically are of large amplitude. The $f - I$ curve associated with an SNIC bifurcation is continuous at I_{SNIC} (Fig. 2b). Ermentrout (1996) has shown that neurons that oscillate through an SNIC bifurcation have type I phase response curves that are strictly of one sign.

A Hopf bifurcation can arise when the v - and w -nullclines only intersect once in a neighborhood of the local minimum (Fig. 1b). Suppose when $I_{ext} = 0$, this single intersection (fixed point) is on the left branch. This fixed point is asymptotically stable. Linearization at it would show that the eigenvalues of the Jacobian matrix are complex with negative real part. As I_{ext}

Bifurcations Dynamics of Single Neurons and Small Networks, Fig. 1 Nullclines of (1). (a) Typical structure for an SNIC bifurcation. The lower black v -nullcline for $I_{ext} < I_{SNIC}$ has a stable (black circle) and an unstable (black square) fixed points near the local minima and an

unstable (yellow square) fixed point along the middle branch. The upper v -nullcline for $I_{ext} > I_{SNIC}$ has only the unstable (yellow square) fixed point. (b) Typical structure for an Hopf bifurcation. Here there is only one fixed point associated with each cubic

Bifurcations Dynamics of Single Neurons and Small Networks, Fig. 2 SNIC bifurcation diagrams. (a) Stable (solid curves) and unstable (dashed curves) solutions as a function of I_{ext} . Black curves denote fixed points and blue curves periodic solutions. As I_{ext} increases, the two fixed

points that meet at I_{SNIC} are destroyed. At this point a branch of stable periodic solutions arises. See text for explanations for I_1 and I_2 . (b) The $f-I$ curve shows that oscillations begin with arbitrarily low frequency

Bifurcations Dynamics of Single Neurons and Small Networks, Fig. 3 Hopf bifurcation diagrams. (a) A single stable fixed point (black curve) loses stability at a supercritical Hopf bifurcation point spawning the branch

of stable periodic solutions. (b) The $f-I$ curve shows that oscillations begin with a frequency that is bounded from below away from zero

increases, the v -nullcline moves up and the fixed point moves toward the local minimum and eventually occurs on the middle branch. The eigenvalues depend continuously on I_{ext} and their real parts become smaller in absolute value. At some point, $I_{ext} = I_{Hopf}$, after the fixed point has moved to the middle branch, the eigenvalues at the linearization are pure imaginary. For $I_{ext} > I_{Hopf}$, the eigenvalues have positive real part. A Hopf bifurcation occurs at I_{Hopf} resulting in the creation of a periodic orbit. There are two distinct types of Hopf bifurcations: supercritical which produce stable periodic solutions and subcritical which produce unstable ones. Figure 3a shows the bifurcation diagram associated with a supercritical Hopf bifurcation. The amplitude of oscillations just after bifurcation is small. The frequency of oscillations just above the Hopf bifurcation points is bounded from below resulting in a

discontinuous $f-I$ curve (Fig. 3b). Neurons that oscillate through a Hopf bifurcation mechanism typically have a type II phase response curve that is of both signs.

In some neuron models, the subcritical Hopf bifurcation is often found in conjunction with another bifurcation called the saddle node of periodic orbits (SNPO) bifurcation. Figure 4 shows such a case where the branch of unstable orbits extends from I_{Hopf} for decreasing values of I_{ext} . Surrounding the branch of unstable periodic orbits is a branch of stable periodic orbits of larger amplitude. The stable and unstable periodic branches come together at $I_{ext} = I_{SNPO}$ which destroys the two orbits. As the bifurcation diagram shows, for $I_{SNPO} < I_{ext} < I_{Hopf}$ bistability exists between the stable fixed point on the middle branch and the larger amplitude periodic orbit. Starting at the stable rest state, as I_{ext} is increased

Bifurcations Dynamics of Single Neurons and Small Networks, Fig. 4 Subcritical Hopf bifurcation diagram. A single stable fixed point (black curve) loses stability at a subcritical Hopf bifurcation point spawning the branch of unstable periodic solutions. That unstable branch merges at I_{SNPO} with a branch of stable periodic orbits. The interval $I_{SNPO} < I_{ext} < I_{Hopf}$ is a region of bistability in that both a stable fixed point and a stable periodic solution exist

past the Hopf bifurcation point, the solution suddenly changes to a large amplitude periodic orbit. Once on this branch of large amplitude solutions, decreasing I_{ext} shows an example of hysteresis whereby the stable branch of periodic solutions exists over a range where the stable fixed points also do.

Variations in different parameters besides I_{ext} can lead to bifurcations. For example, in a model associated with the circadian rhythm, *per1* neurons in the suprachiasmatic nuclei undergo a subcritical Hopf bifurcation as the maximal conductance of their calcium channel, g_{Ca} , is increased (Belle et al. 2009). Belle et al. show that as g_{Ca} is increased, an asymptotically stable rest state undergoes a subcritical Hopf bifurcation leading to oscillations during only a certain phase of the circadian rhythm. They also show that a second Hopf bifurcation can arise during a phase corresponding to daytime in which a highly depolarized resting state becomes stable. Mathematically, the mechanism for the creation and control of oscillations is exactly the same whether the bifurcation results from changes in g_{Ca} as in this case or from I_{ext} as shown in Fig. 4.

Bifurcation analysis is also a primary tool in understanding bursting oscillations where a neuron exhibits a sequence of (relatively) high-frequency spikes, followed by a (relatively) long

interburst interval. The main idea here is to exploit the difference in time scales between the high-frequency spikes and the long interburst interval to define fast and slow variables. Consider the following set of three first-order equations:

$$\begin{aligned} x' &= f_1(x, y, z) \\ y' &= f_2(x, y, z) \\ z' &= \epsilon g(x, y, z). \end{aligned} \quad (3)$$

The small positive parameter ϵ implies that x and y are fast variables and z is the slow variable. To use bifurcation analysis, set $\epsilon = 0$ in Eq. 3 and note that now $z' = 0$, implying that z will not change. This means that z will act as a parameter in the fast equations for x' and y' . The fast subsystem can now be studied with z acting as a bifurcation parameter to see what, if any, bifurcations exist. For each z , the equations $f_1(x, y, z) = 0$ and $f_2(x, y, z) = 0$ are the nullclines of the fast subsystem. They form null surfaces in the full three-dimensional phase space. Intersections of any two null surfaces form curves of fixed points of the fast subsystem and their bifurcations can readily be studied. The mathematical technique of singular perturbation theory then shows that solutions to the actual $\epsilon > 0$, but small, problem lie close to the null surfaces except for times when they make very fast transitions between different null surfaces. The location where these fast transitions occur is computable through bifurcation and singular perturbation analysis. Rinzel (1985, 1987) first used these ideas to mathematically classify different types of bursting in single-cell models. Figure 5 shows an example of square wave bursting bifurcation diagram which illustrates this type of analysis. See (Izhikevich 2000) for a rigorous mathematical exploration of bursting in single neurons or (Ermentrout and Terman 2010) for an overview of several important types of bursting arising in neuroscience.

Bifurcations in Small Neuronal Networks

Just as certain parameters intrinsic to a neuron can determine whether an individual neuron can oscillate, these parameters can also do the same for a

Bifurcations Dynamics of Single Neurons and Small Networks, Fig. 5 Bifurcation diagram associated with square wave bursting. The variable z acts as a parameter for the $\epsilon = 0$ fast subsystem of (3). As z is increased along the upper branch of fixed points (upper solid black curve of the Z-shaped curve), the fixed point undergoes a subcritical Hopf bifurcation. The unstable periodic branch merges with a stable branch of periodic solutions at z_{SNPO} . The stable branch of periodic solutions terminates at a homoclinic bifurcation point at z_{Hom} . The actual flow of (3) for ϵ small is graphically depicted. The red lines pointing left (right) indicate that the solution closely follows the lower (upper) branch of the Z-shaped curve as z slowly decreases (increases). The green lines indicate the fast transitions between the upper and lower branches of the Z-shaped curve. Magenta arrows between the stable periodic branches indicate the fast spiking portion of the burst

coupled network of neurons. A small network of cells may not be able to oscillate unless some or all of the individual cells can. Thus, whatever bifurcation causes the individual cell to oscillate may, in turn, cause the network to be rhythmic. Changes in intrinsic parameters having nothing to do with the existence of oscillations can also lead to bifurcations in network output. For example, Zhang et al. (2009) show that increases in the maximal conductance of an A-current in a postsynaptic cell can cause the cell to go through a sequence of border collision bifurcations (Nusse et al. 1994), resulting in a cascade of different phase-locked solutions.

In networks, many interesting bifurcations occur with changes in synaptic parameters. Consider a network of two mutually coupled spiking neurons governed by the integrate and fire model and connected by alpha synapses $g_{syn}\alpha^2te^{-\alpha t}$. Here g_{syn} governs the strength and α the speed of the synapse. The phase ϕ at which one cell fires with respect to the other can be used to define a

function whose roots correspond to phase-locked periodic solutions. For this model of two identical cells, both the synchronous ($\phi = 0$ or 1) and antiphase ($\phi = 0.5$) solutions exist for both excitatory ($g_{syn} > 0$) and inhibitory ($g_{syn} < 0$) coupling. Van Vreeswijk et al. (1994) showed that these solutions change stability through a pitchfork bifurcation as the parameter α changes; at the pitchfork bifurcation point, three branches emerge from one. In particular, for excitatory synapses, increases in α make the antiphase solution bifurcate from being stable to unstable (Fig. 6a). At the bifurcation point, a new stable out-of-phase solution arises; by symmetry there are two such solutions. Further increasing α causes these new curves of out-of-phase solutions to come closer to the curve corresponding to the synchronous solution. Note in this case, that while the synchronous solution is always unstable, as α increases and the synapse becomes faster, the phase of locking ϕ tends to synchrony. The opposite happens for inhibitory synapses (Fig. 6b). As α increases and the synapse is made faster in its rise and decay, the antiphase solution undergoes a pitchfork bifurcation taking it from unstable to stable. The curves of out-of-phase solutions that are born are unstable. The synchronous solution is stable for all values of α , but its basin of attraction shrinks as α increases.

A common way to find bifurcations in a neuronal network is to define a Poincaré return map or a time T map. The Poincaré map records the values of relevant variables along a defined hyperplane in the mathematical phase space. The time T map records the values of appropriate variables at every time nT , for $n = 1, 2, 3, \dots$. In either case, a fixed point of the map corresponds to a periodic solution of the network. In this way, mathematical tools to study bifurcations of fixed points of maps (discrete dynamical systems) can be used to study bifurcations of periodic solutions of networks. For example, in a model consisting of an excitatory cell reciprocally coupled to an inhibitory cell whose synapse exhibits short-term synaptic depression, Bose et al. (2001) showed how changes in the maximal synaptic conductance of the inhibitory synapse give rise to saddle-node bifurcations of fixed points of a one-dimensional

Bifurcations Dynamics of Single Neurons and Small Networks, Fig. 6 Bifurcation diagram as a function of synaptic speed, (Adapted from Van Vreeswijk et al. (1994)). (a) For excitatory synapses, as the synaptic speed increases, the stable antiphase solution at $\phi = 0.5$ undergoes a pitchfork bifurcation. The new curve of stable

out-of-phase solutions shows that solutions approach synchrony as the synapse gets faster. (b) For inhibitory synapses, the synchronous solution is always stable. The antiphase solution stabilizes by increasing α though the pitchfork bifurcation point

return map (Fig. 7). The fixed points of the map correspond to different oscillatory solutions of different frequency. Solutions on the upper branch are controlled by parameters that are intrinsic to the excitatory cell and are of high frequency. The high frequency causes the inhibitory synapse to remain in a depressed state and never recover. Solutions on the lower branch correspond to low-frequency solutions with a long interspike interval. Because of this long interval, the depressing synapse has a chance to recover between spikes and the synaptic current to the excitatory cell at each spike is large. Here the frequency is controlled by a parameter governing the decay of inhibition. Note that this network also exhibits bistability and hysteresis similar to what was seen to occur in certain single-neuron models. Perturbations can cause the solution to switch between different oscillatory solutions as seen in Fig. 7. The switch is a consequence of the bifurcation structure, but is not in and of itself a bifurcation.

As is suggested by the prior example, bifurcations in networks of neurons are also closely related to the issue of what sets of parameters control the oscillatory state. This is especially true in central pattern generating (CPG) networks where the existence of oscillations is a given. What is more relevant is what controls the existence of oscillations and their frequency. For example, in a network of two cells mutually coupled by fast inhibitory synapses, Skinner et al. (1994) describe circumstances under which the synaptic threshold is of importance in

controlling the frequency of antiphase, half-center oscillations. They define the terms intrinsic escape, intrinsic release, synaptic escape, and synaptic release to indicate different ways in which the oscillators can switch orientations from being active to silent and vice versa. The synaptic threshold turns out to be irrelevant in the intrinsic escape or release mode but is highly relevant in the synaptic escape or release mode. Understanding how the synaptic threshold can play this role relies, in part, on bifurcation dynamics associated with single cells. For single cells it was earlier shown that increasing I_{ext} causes the stable solution to bifurcate from being a rest point to an oscillatory one by shifting the v -nullcline up in the phase space and removing a fixed point on its left branch. In this two-cell network, the removal of an inhibitory synaptic current to the postsynaptic cell acts similarly to increasing I_{ext} in a single cell by shifting the v -nullcline up in phase space and removing an intersection of the v - and w -nullclines. Thus, although there is not a bifurcation in the network as the result of the application or removal of a synaptic current, the mechanism by which the postsynaptic cell fires is readily understood as a result of single-neuron bifurcation analysis. The possible application or removal of inhibition occurs only when the synaptic threshold is crossed. When the individual cells are modeled as relaxation oscillators (with cubic-shaped v -nullclines), then the fast transition between the silent and firing states effectively occurs at the local minima and maxima of the cubic nullcline. Thus, when the synaptic threshold

Bifurcations Dynamics of Single Neurons and Small Networks, Fig. 7 Dynamics of an excitatory-inhibitory network. *Upper panel* shows bifurcation diagram as a function of maximal inhibitory conductance g_{inh} . The two branches of stable periodic solutions are connected by an unstable branch. *Lower panel* shows voltage trajectories (E excitatory, I inhibitory) with g_{inh} chosen at the value of the dotted line in *upper panel*. The solution starts off at high frequency along the upper branch. A brief perturbation given to the inhibitory cell temporarily suppresses its activity allowing its synapse to recover from depression and strengthen. In turn, this causes the solution to switch to a lower frequency periodic orbit along the lower branch

lies between these two extrema, the threshold is not relevant for controlling frequency as small changes in its value have little effect on the time spent above or below it. On the other hand, if the synaptic threshold intersects either the left or right branch of the cubic, then small changes in its value can have an effect since the cell's trajectory evolves slowly there; that the evolution is slow is a consequence of the assumption of relaxation oscillations. It is through the scaffold of single-

cell bifurcation analysis and fast/slow time scale decomposition that Skinner et al. are able to define intervals for the synaptic thresholds that demarcate intrinsic versus synaptic escape/release mechanisms and thereby control the frequency of oscillations.

A more complicated example of using bifurcation analysis is found in a model of a respiratory CPG due to Rubin et al. (2009). The authors consider a four-cell network of excitatory and inhibitory cells and are interested in understanding transitions between oscillatory patterns that correspond to different phasic states of the respiratory rhythm. By using fast/slow time scale analysis, they show how to identify certain transitional curves associated with the fast subsystem. These curves lie on equilibrium surfaces (null surfaces) of the fast subsystem. In the problem considered, there are relevant equilibrium surfaces corresponding to cells being either in the active or inactive state. When the trajectory of the system reaches one of these transitional curves, there is a switch from inspiration to expiration or vice versa. The transitional curves are themselves defined because they satisfy certain bifurcation conditions for fixed points of the fast subsystem. Through their analysis, the authors show how changes in the maximal conductance of a persistent sodium current in one of the cells play a major role in controlling the frequency and duty cycle of oscillations within the network. They also show how changing the total synaptic drive to individual cells modulates the bifurcation diagram again resulting in an understanding of how frequency and duty cycle change. The interested reader is referred to (Rubin et al. 2009) to see further details.

Concluding Remarks

Bifurcations at the single-neuron level often focus on understanding how a single fixed point is created or destroyed or how it gains or loses stability. Different kinds of bifurcations imply the existence of different kinds of oscillatory solutions, each possessing different properties. As a single-neuron model becomes more complicated, say

for describing a bursting neuron, bifurcations occurring in a fast subsystem help to build the skeleton on which the dynamics of the full system can be understood. In networks, the bifurcation parameter can be either intrinsic to a cell or related to one of the synapses. Bifurcations within them are often understood by knowing the bifurcation possibilities of single neurons. But networks have the potential to be much richer and complicated in their bifurcation structure. An important concept highlighted above is that bifurcation analysis can reveal how certain parameters determine which network elements control the behavior in the network. Interestingly, a bifurcation occurring as a result of a change in an intrinsic parameter may imply that a synaptic mechanism becomes relevant for controlling the network output, or vice versa.

Bifurcations of the type described here are associated with steady-state solutions (fixed points or periodic orbits) of differential equations. They are local in the sense that the information obtained from the bifurcation only provides information in a neighborhood of the bifurcation point. While this neighborhood may in fact be mathematically large, it is important to keep in mind that the entire set of possible solutions in the global phase space are not determined through local bifurcations. Nonetheless, bifurcation analysis is a powerful tool for understanding the dynamics of neurons and the networks in which they participate.

Bifurcations, Neural Population Models and

Thomas R. Knösche

Max Planck Institute for Human Cognitive and Brain Sciences, Leipzig, Germany

Definition

In neural population models (NPMs), as in dynamical systems in general, smooth changes in system parameters, for example, coupling strength, input levels, and time constants, may result in sudden qualitative changes in system

dynamics, such as the occurrence or disappearance of oscillatory or chaotic behavior. Such phenomena are referred to as bifurcations and are interesting because they may account for switching phenomena, which are common in both brain signals and organisms' behavior.

Detailed Description

Depending on their particular parameter set, NPMs experience different asymptotic dynamic behaviors characterized by constant output, harmonic (i.e., sinusoidal) or nonharmonic oscillations, which can be periodic or quasiperiodic (i.e., the signal repeats itself approximately, but not exactly), and even chaotic behavior (Frascoli et al. 2011; Spiegler et al. 2010, 2011). The transitions in parameter space between these qualitatively different states are called bifurcations (see Breakspear and Jirsa 2007). They partition the parameter space into regions with different dynamics. Their analysis is of fundamental importance for the description of the behavior of neural systems, which often features the transition of gradual changes in some variables into sudden qualitative changes in system behavior. Bifurcation diagrams are an important utility for the investigation of bifurcations. They show the stable and unstable fixed points (i.e., points, where the time derivatives of the state variables are zero; also referred to as equilibrium points) and limit cycles (i.e., closed trajectories in state space) as a function of one or more system parameters (see Fig. 1). In the following, we will give a brief overview on types of bifurcations that are relevant for neural population models. Then we will demonstrate, using the example of the Jansen-Rit model (Jansen and Rit 1995), how bifurcation analysis characterizes the dynamic fingerprint of a neural population model.

Types of Bifurcations

There is a great variety of different types of bifurcations (see also Guckenheimer 2007; Breakspear and Jirsa 2007). Depending on whether or not it

can be identified just by stability analysis in a small vicinity of a fixed point, a bifurcation is termed local or global. In addition, bifurcations are characterized by their codimension, which is the number of independent parameters that need to be varied for the bifurcation to occur. Consider the bifurcation diagram in Fig. 1, where the asymptotic behavior of the pyramidal cells' membrane potential is plotted versus a single system parameter, namely, the mean input to the pyramidal cells. It shows a number of codimension 1 bifurcations (see figure legend).

Local (or subtle) bifurcations are characterized by a change of asymptotic stability, that is, fixed points and limit cycles suddenly change stability upon smooth change of a system parameter. They can be analyzed by looking at the, generally complex, eigenvalues of the system's local linearization (Jacobian matrix). If the real parts of one or several of the eigenvalues change sign, the local stability of the system is altered and a bifurcation occurs. Types of local bifurcation that are most often identified in neural population models include Andronov-Hopf (AH) as well as saddle-node (SN), saddle-focus (SF), and saddle-saddle (SS) bifurcations (Grimbert and Faugeras 2006; Spiegler et al. 2010; Touboul et al. 2011). Further important local bifurcations are the pitchfork, transcritical, and period-doubling bifurcations (see Breakspear and Jirsa 2007).

AH bifurcations occur if two conjugate complex eigenvalues cross the imaginary axis. They mark the transition between a fixed point (real part is negative) and a limit cycle (real part is positive). Depending on the largest Lyapunov exponent, the bifurcation can be supercritical (i.e., both limit cycle and fixed point are stable) or subcritical (i.e., limit cycle and fixed point are unstable). AH bifurcations give rise to oscillations, which are more or less harmonic, depending on their amplitude and the system's degree of nonlinearity.

SN/SF bifurcations (also called tangential or fold bifurcations) occur if, upon change of a parameter, two fixed points, one unstable (the saddle) and one stable (the node or focus), collide and annihilate each other. When approaching the bifurcation from the other side, this means that two fixed points are suddenly created. At the

B

Bifurcations, Neural Population Models and, Fig. 1 Bifurcation diagram and exemplary solutions of the original configuration of the Jansen and Rit (1995) with no input to the interneurons and time constants 10 and 20 ms for excitatory and inhibitory interneurons, respectively. Solid lines represent stable and dashed lines unstable states. Branches of limit cycles correspond to gray regions bounded by solid lines for stable and dashed

black lines for unstable limit cycles. Bifurcations are indicated by diamonds, triangles, and circles (see legend in inset). For all Andronov-Hopf bifurcations, the eigenfrequencies of the limit cycles are indicated. Different extrinsic input levels on pyramidal cells (black and green vertical lines) result in different behaviors depending on the past of a system's trajectory (blue and red arrows) (Modified from Spiegler et al. (2010))

critical point itself, the fixed points lose asymptotic stability, as they become non-hyperbolic (i.e., the second derivative becomes zero). If both colliding fixed points are saddles, the bifurcation is an SS bifurcation.

Global (or catastrophic) bifurcations have to be studied by considering the vector field outside the local neighborhood of fixed points. They are characterized by a loss of structural stability, that is, fixed points and limit cycles suddenly occur or vanish upon smooth change of a system parameter. Accordingly, the saddle family of bifurcations (see above) can also be considered global, as the two colliding fixed points vanish. One typical

example of a global bifurcation is given by the infinite period bifurcation, where a stable fixed point (node or focus) is connected to a saddle via a particular trajectory, called the heteroclinic orbit. Upon change of the parameter toward the critical point, these two fixed points get closer and closer, until they collide and vanish. Now, the trajectory connecting the former fixed points turns into a periodic orbit, giving rise to sustained oscillations of the system. If approached from the other side, this bifurcation is characterized by a slowing of the oscillation, until at the critical point the period becomes infinite and the periodic orbit is turned into a heteroclinic orbit connecting two fixed

points. Global bifurcations also include homoclinic and heteroclinic bifurcations, in which periodic orbits collide with one or several saddle points, or collisions between more than one periodic orbit.

Examples for higher codimension bifurcations include the following: (1) the Bautin (generalized Hopf, GH) bifurcation, which occurs if an AH bifurcation, upon change of a second parameter of the system, turns from supercritical to subcritical; (2) the Bogdanov-Takens (BT) bifurcation, where AH, SN, and homoclinic curves intersect; and (3) the cusp (C) bifurcation, where two branches of saddle-node bifurcation curve meet tangentially, giving rise to hysteresis phenomena. For more information, refer to Guckenheimer (2007) and Kuznetsov (2004).

Bifurcations of the Jansen-Rit Model

The Jansen-Rit model has been investigated by Touboul and Faugeras (2007) as well as Spiegler et al. (2010, 2011) by generating codimension one bifurcation diagrams, where the membrane potential of the pyramidal cells is plotted as the relevant state variable against the constant input level to the same cell population (Fig. 1).

For the original parameter configuration of Jansen and Rit, the following dynamics occur, while gradually increasing the pyramidal cell input: At very low input levels, only one stable fixed point (node) exists (Sect. I in Fig. 1). At about -1.2 mV, two unstable fixed points (saddles) appear in an SS bifurcation (Sect. VIII). The system still remains monostable with one stable fixed point. With further increase of the input level to about -0.5 mV, one of the saddles undergoes a subcritical AH bifurcation, resulting in an unstable limit cycle and stable focus (sect. VII). The system is now bistable. At about 3 mV the stable focus undergoes a supercritical AH bifurcation, giving rise to stable harmonic oscillations (sect. VI). Further increase to about 3.5 mV lets the stable node and the unstable saddle collide, and a periodic homoclinic orbit is born in an infinite period bifurcation (sect. V). In another global bifurcation, this orbit collides at about 4.5 mV with unstable limit cycle originating

from the subcritical AH bifurcation. The cycles vanish and the system's only remaining stable state is the stable limit cycle (sect. III), which turns into a stable node by another supercritical AH bifurcation at about 10.5 mV.

This exemplary bifurcation scheme is subject to drastic change, if the other system parameters are varied, which has been shown by systematic sampling of the parameter space (Spiegler et al. 2010) and by characterization of higher codimension bifurcations (Touboul and Faugeras 2007). In addition to the SN and AH bifurcation manifolds, Touboul and Faugeras (2007) found some codimension two and three bifurcations for the Jansen-Rit model, namely, C, BT, and GH bifurcations.

Bimolecular Reactions, Modeling of

Stuart Edelstein
Babraham Institute, Cambridge, UK

Definition

A bimolecular reaction refers to the chemical combination of two molecular entities in a reaction that can be considered either reversible or irreversible. The reaction can involve two chemically distinct molecules, e.g., $A + B$, or two identical molecules, e.g., $A + A$. The reaction can be characterized with respect to association and dissociation rate constants, which also define the equilibrium constant. However, it is also possible to establish the equilibrium constant without direct knowledge of the rate constants. For many applications to biological systems, one or both of the components possess multiple reaction sites and/or distinct conformational states, adding levels of complexity that must be considered for a complete description of the system.

Detailed Description

For computational neuroscience encompassing the molecular level, bimolecular reactions are

encountered for virtually all topics considered. Neurons and their accompanying cells of other classes are living entities with a complete array of biochemical reactions, most of which are not specific to the nervous system, such as the full complement of metabolic enzymes. Enzyme-substrate reactions are one form of bimolecular reactions, but will not be considered here, since another chapter that included this topic was recently completed (Endler et al. 2012). For reactions in individual neurons, only small numbers of molecules are involved in many cases and stochastic principles must be applied to consider the reactions appropriately. This subject will not be treated, but general principles are well described elsewhere (Steinfeld et al. 1989), along with a detailed description for ligand-gated channels based on terminologies that are presented here (Edelstein et al. 1996). The focus for this entry is on ligands binding to multisite proteins that can exist in more than one functionally distinct conformational state, as commonly occur for allosteric membrane proteins (Edelstein and Changeux 2010) and other allosteric regulatory proteins, such as calmodulin (Stefan et al. 2008). These phenomena are most efficiently represented by the formalism of the Monod-Wyman-Changeux (MWC) model (Monod et al. 1965; Edelstein et al. 1996; Changeux and Edelstein 2005).

Formalism for Two Conformational States

The MWC model defines a multisite (oligomeric) protein with two conformational states, T and R related by the allosteric constant, L_i , where $L_i = [T_i]/[R_i]$. Here “i” refers to the number of ligand molecules bound up to the limit of “n” molecules, usually equivalent to the number of subunits in an oligomeric protein. Ligand is represented by “X,” with distinct dissociation equilibrium constants for the T and R states: K_T and K_R . The model is formulated such that the T state is favored in the absence of ligand ($L_0 \gg 1$), but the R state binds the ligand more tightly ($K_R \ll K_T$). Hence, typically for a dimer with two ligands bound, $L_2 \ll 1$. Each reaction equilibrium constant is the ratio of the appropriate kinetic constants, $k_{\text{off}}/k_{\text{on}}$. Because

more than one binding site is involved, statistical factors come into play. For example, for a ligand binding to an unliganded dimer ($n = 2$), the on rate must be increased by a factor of two, since two sites are available on the dimer. Similar reasoning applies to the dissociation of ligand from a fully or partially saturated oligomer. Generally, for a protein with n sites and i ligands bound, the binding of an additional ligand is modified by the statistical factor $(n - i + 1)/i$. The binding reactions are illustrated in Fig. 1, along with the equations for occupancy and fraction of molecules in the R state. Finally an energy diagram is presented

Equations for occupancy ($\bar{Y}$) and fraction in R state ($\bar{R}$):

$$\bar{Y} = \frac{\alpha(1 + \alpha)^{n-1} + Lc\alpha(1 + c\alpha)^{n-1}}{(1 + \alpha)^n + L(1 + c\alpha)^n}$$

$$\bar{R} = \frac{(1 + \alpha)^n}{(1 + \alpha)^n + L(1 + c\alpha)^n}$$

Energy diagram for dimer with two-states:

Fig. 1

in the figure to reveal how the kinetic constants are related to the thermodynamic parameters in terms of activation barriers fixed by linear free energy relations (Edelstein et al. 1996).

Limitations

The concepts presented here do not distinguish between the free and the total concentrations for the ligand in question. Commonly the total concentration is assumed to be effectively indistinguishable from the free concentration, but under conditions that approximate the physiological state, this assumption is often inapplicable. In that case, the binding of ligand can cause a significant change in the free concentration (a phenomenon known as “ligand depletion”) and the appropriate corrections must be introduced, since the effects may be substantial (Edelstein et al. 2010).

Definition

Low back pain can arise from a wide range of inciting conditions and pathologies in the lumbar and sacral spines. Symptoms can remain localized to the axial spine but also can extend to the torso and upper back, buttocks, legs, and feet, depending on which tissues in the spine are affected and the extent of the related pathology. The most common spinal tissues involved in producing low back pain are the intervertebral disc, facet joints, nerve roots, and musculature. Many different biomechanical models have been developed in order to study low back pain. In particular, such models mimic the mechanical loading to the spine and/or its isolated tissues that serve as sources of pain, and define the local tissue biomechanics for various normal and abnormal spinal

loading conditions. Biomechanical models focus on describing and informing different aspects of the cascades related to tissue loading, mechanical responses, physiological cascades that are initiated and maintained, and the symptom response.

Detailed Description

Biomechanical models can be categorized into several different types: animal and human cadaveric models, in vivo animal models, and computational and mathematical models. Over the years, each of these modeling approaches has incorporated biomechanical techniques and together provides a complementary and increasingly more detailed insight about the causes, consequences, and complications associated with low back pain.

Cadaveric Models

Cadaveric models of both humans and other species have formed the basis of the early efforts in biomechanical modeling. They most often describe the spine's kinematic and kinetic response to loading, as well as the mechanical response that individual tissues undergo during spinal loading. In addition to defining the anatomical, material, and structural relationships between the various tissues in the spine, these models have defined how such relationships vary with various loading configurations in the context of normal motions, injury, degeneration states, and following surgical treatments (White and Panjabi 1990; Winkelstein 2012). The main findings have defined injury tolerance for failure of different tissues and the physical consequences of repetitive loading to certain tissues, such as the production of ligament laxity, loss of disc height, and increased motion (Shapiro and Risbud 2013).

In Vivo Animal Models

Despite the potential differences in anatomy, scaling, and physiology between animals and humans, in vivo models have tremendous utility

for biomechanical modeling of LBP (DeLeo and Winkelstein 2002; Winkelstein 2011), especially given the ethical and financial advantages they offer while also providing meaningful insight on the mechanics of spinal tissues and the related physiological and symptom responses. Animal models of nociception help in understanding neural mechanisms of pain from the spine, such as arthritis, discogenic pain, and radicular nerve root injury, all of which can lead to the development of acute and chronic LBP (Deleo and Winkelstein 2002; McMahon and Koltzenburg 2005; Jaumard et al. 2011).

The earliest studies using animal models of chronic back pain involve direct surgical manipulation of the sciatic nerve including sciatic cryoneurolysis (DeLeo et al. 1994); sciatic nerve transection, ligation, or crush (Przewłocka et al. 1999; Obara et al. 2003); partial nerve injury (Seltzer et al. 1990); chronic constriction injury (Bennett et al. 2003); and L5/L6 spinal nerve ligation (Colburn et al. 1999). Although those models have been important for defining the cascades that lead to pain following neural injury in the spine, they have not standardized the role of biomechanics. More recent work in the rodent has defined the role of tissue loading for nerve root and disc injuries (Iatridis et al. 1999; DeLeo and Winkelstein 2002; Winkelstein et al. 2002; Jaumard et al. 2011; Showalter et al. 2012). Only recently, with the advances in measurement technologies, have local tissue mechanics been able to be incorporated in such models to relate specific injury and loading environments to tissue responses, neuroimmune cascades regulating pain, and resulting symptoms of pain.

Computational/Mathematical Models

Due to the complexity of modeling injury and pain from tissue loading, cadaveric and in vivo modeling have only limited utility for modeling LBP. As such, computational models have been developed based on anthropomorphic measurements that permit many loading configurations to be tested. Such models extrapolate the

biomechanics of the lumbar spine for loading conditions that cannot be tested using live subjects, such as injury scenarios from vehicle impacts, sports injury, and exposure to high-frequency vibrations. This is particularly relevant when modeling LBP in which ethical considerations limit the exposures that are allowed.

Biomechanical computational models can be grouped as lumped-parameter, multibody, or finite element models (Liang and Chiang 2006). Lumped-parameter models (Fig. 1) are generally limited to only one-dimensional analysis, simulating the human body as an assembly of concentrated masses, representing different parts of the body, connected by springs and dampers that simulate the viscoelastic properties of the biologic tissues. The lumbar spine can be represented as masses for the vertebrae connected by a spring and damper in parallel to simulate the intervertebral disc (Keller et al. 2002). Multibody models consist of rigid bodies connected by hinges and/or ball-and-socket joints and can be used to study the kinematics and kinetic response of the body to a direct or indirect mechanical excitation (Ma et al. 1995).

Finite element (FE) models are the most complex since they mimic the anatomical and material properties of the spinal tissues and their relationships based on different loading scenarios and motions. Several FE models have been developed to evaluate spine biomechanics and simulate clinical procedures. Such models were designed to understand how changes in the spine, such as disc degeneration, osteophytes, disc arthroplasty, facetectomy, or laminoplasty, affect the local mechanical response of its tissues (bone, ligament, cartilage), as well as the overall spinal biomechanics (Rohlmann et al. 2007; Rundell et al. 2008; Zhang and Teo 2008; Kuo et al. 2010). Other FE models provide utility for evaluating tissue loading from spinal biomechanics during nonphysiological injurious loading (Sairyo et al. 2005; Kitagawa et al. 2006; El-Rich et al. 2009). While these approaches have become tremendously intricate, with detailed physiological and mechanical processes captured in the models, there are currently no such models that can

Biomechanical Model of Low Back Pain,

Fig. 1 Example of a lumped-parameter model of the rodent used to evaluate spinal kinematics and kinetics in whole body vibration along the spine's axis. The three masses ($M1$, $M2$, $M3$) simulate the mass of the three body segments. Springs (K) and dampers (C) simulate the viscoelastic interactions between the masses and the masses and the vibrating platform

simulate the nociceptive processes that are initiated or modulated by spinal loading as it relates to pain.

Overall, computational models help to understand how the biomechanics of the lumbar spine and its associated spinal tissues can be altered and enable inferences about the development of low back pain. The outcome of these models also provides means to design interventions, devices, and therapeutic interventions to protect, repair, and treat the lumbar spine in order to avoid and/or reduce the symptoms intrinsic to low back pain.

Definition

Biomechanical modeling of traumatic brain injury (TBI) refers to the use of a computer model of the human head to simulate brain mechanical responses when the head is subjected to external blunt impact or blast exposure. The resulting tissue responses such as strain, strain rate, and pressure in specific regions of the brain can then be used to predict the occurrence of TBI.

Detailed Description

A computational head injury model is composed of three basic constituents: model geometry, boundary conditions, and tissue material properties. With properly measured impact loading conditions as input for simulation, whole-brain biomechanical responses can then be estimated.

The most widely used method to model the biomechanical responses of TBI is through a finite element (FE) model of the human head (Yang et al. 2006) (illustrated in Fig. 1). This technique discretizes the spatial domain of the head, including the brain, skull, cerebrospinal fluid, falx, tentorium, and other intracranial components, into small interconnected “elements” via a process called meshing. The continuum deformation field

Biomechanical Modeling of Traumatic Brain Injury, Fig. 1 The Worcester Head Injury Model (WHIM) showing the head exterior features (a), intracranial

components (b), and transcallosal white matter (WM) fiber tracts (c) (Zhao et al. 2016)

of the brain is then represented by the displacements of the discretized element nodes. These nodal displacements are interrelated to each other in a large linear system of equations. The structure of the linear system of equations depends on how the nodes are interconnected, or, the connectivity of the FE mesh. The stress-strain relationship of every component of the model, including the brain and skull, that governs the biomechanical behavior of the underlying material is embedded into the coefficients of the linear system of equations. For moderate and severe blunt head/brain injury as well as blast-induced brain injury where skull deformation is anticipated, the skull is treated as nonrigid to allow for deformation. In contrast, for mild TBI (mTBI) in which skull deformation is often assumed to be negligible, the skull is idealized as a rigid body to simplify the linear system of equations.

Applying loading conditions obtained from external head impact such as recorded linear and rotational acceleration time history profile in the case of blunt-induced TBI, solutions to the linear system of equations are then calculated for the duration of the head impact. The nodal displacement solutions are subsequently used to calculate stress, strain, and pressure for each element. The resulting brain biomechanical responses are further used to predict the occurrence of injury. It is generally believed that the magnitude of strain

and its rate (i.e., how fast brain tissue deforms) are both important factors behind the mechanisms of TBI (King et al. 2003).

Model Validation

The accuracy of the FE model depends on a number of factors, including the material properties of the brain, falx, tentorium, etc., the brain-skull interfacial condition (such as whether to allow relative movement along the brain surface), and the quality and density of the brain mesh. To gain confidence in model-estimated brain responses, it is important to first validate the head injury model. This is performed by comparing the estimated brain tissue deformation with measurements from cadaveric head impact tests, often conducted at very high impact magnitudes (Hardy et al. 2007). More recently, biomechanical data from live humans measured from magnetic resonance imaging (MRI) are also becoming available (Bayly et al. 2012). They provide additional data for validation at the other, low end of the impact severity spectrum far away from the injury level (Zhao et al. 2018). Using the recorded impact acceleration profiles as input, the relative brain-skull displacement or strain response history (for the cadaveric and live human data, respectively) are generated from the given model under scrutiny. The degree of model-experiment response

agreement indicates the quality of model validation. When a model is successfully validated at both ends of the impact severity spectrum, the confidence in model simulation for the majority of real-world head impacts such as seen in contact sports can then be improved.

The brain material properties are the most frequent target for adjustment in order to satisfy and maximize model validation performance. In part, this is because there is no consensus at present on the most appropriate material model or property constants to use for impact simulation (de Rooij and Kuhl 2016; Yang et al. 2006). Despite decades of active research, a large variation exists in the literature resulting from differences in testing methods and conditions (Cheng et al. 2008), in vitro test conditions (Hrapko et al. 2008), in vitro vs. in vivo tests (Chatelin et al. 2010). Reviews on imaging methods (Bayly et al. 2012; Di Ieva et al. 2010), constitutive models (de Rooij and Kuhl 2016; van Dommelen et al. 2009), and the diverse material properties used in head injury models (Yang et al. 2006) also exist. This provides room for model parameter adjustments.

The brain mesh resolution is also a significant factor affecting the accuracy in brain response simulation. The dependency on mesh resolution is investigated through a “mesh convergence” study, in which multiple mesh resolutions of the brain or head are generated to simulate an identical impact. Mesh convergence is achieved when the solution no longer changes significantly with further mesh refinement.

Incorporation of Neuroimaging

Head injury models have been continually developed and improved over the last several decades. Among many efforts, recent advancements include the incorporation of neuroimaging for brain biomechanical modeling. For example, subject-specific FE models of the heads are generated based on high-resolution neuroimages of individual MRI volumes (Ji et al. 2015). In addition, whole-brain white matter (WM) tractography is incorporated to estimate stretches along WM fibers for injury analysis, and advanced anisotropic material properties of the

WM are also integrated to improve model biofidelity (Giordano and Kleiven 2014; Zhao et al. 2016). A multiscale modeling approach can be used to mitigate the mesh-image resolution mismatch (Lytton et al. 2017; Zhao and Ji 2018).

While a sophisticated head injury model is able to provide detailed brain strain maps for a given head impact, not all information is utilized for injury analysis at present. Most existing studies only employ the peak strain magnitude of the whole brain or a volume fraction of the brain above a certain threshold to predict injury. Conceptually, this is analogous to down-sampling the detailed strain map into a single scalar variable. Inevitably, loss of information ensues.

This limitation is now recognized, and efforts to utilize advanced neuroimaging to facilitate the sampling of the simulated brain responses are emerging. A potential remedy is to use responses in specific brain regions (e.g., corpus callosum or brainstem, vs. the whole brain) or a collection of brain regions (e.g., the 50 deep WM regions based on a well-developed neuroimage atlas (Zhao et al. 2017)) and their interconnections or neural pathways obtained from whole-brain tractography. The latter approach enables characterizing the distribution of peak brain responses. Potentially, this could allow modern feature-based machine learning classification for improved TBI detection (Cai et al. 2018) (vs. mostly univariate logistic regression in current TBI biomechanical studies).

Definition

BioModels Database is a public repository for mathematical models of biological processes. It provides access to models described in peer-

reviewed scientific literature, as well as those generated automatically from pathway resources. Model components, structure, and behavior of a large proportion of models in the database are thoroughly checked. This manual procedure ensures model correspondence with the original publication. Furthermore, model components are semantically enriched with cross-references to external ontologies and other relevant data resources. Models are exported in various formats, including SBML. Graphical representations of reaction networks are also provided. Simple and advanced search options are available to facilitate model retrieval. BioModels Database can be accessed through a web interface and programmatically using web services.

All models are distributed under the terms of the Creative Commons CCO Public Domain Dedication License, ensuring that models are available free for use, modification, and distribution for any user.

Detailed Description

BioModels Database (Li et al. 2010) hosts mathematical models of varying complexity, from simple biochemical reaction systems to larger and complex dynamic models, metabolic network models, and flux balance analysis (FBA) models. It is a part of the [BioModels.net](http://biomodels.net) initiative (<http://biomodels.net>; Le Novère 2006), which aims to help modelers to exchange and integrate existing models, through the use of established and shared standards.

Model Categories

BioModels Database holds two major sets of models: (A) models described in scientific literature and (B) models automatically generated from pathway resources.

A. Models published in peer-reviewed scientific literature.

These models are included in the resource either directly by a team of curators or after direct submission by modelers or authors. Models have

also been contributed through established collaborations with other model repositories, such as the former SBML model repository (Caltech, USA), JWS Online (<http://jjj.biochem.sun.ac.za>), the Database Of Quantitative Cellular Signaling (DOQCS) (<http://doqcs.ncbs.res.in>), and the CellML Repository. More importantly, several publishers of scientific journals recommend deposition of models to BioModels Database in their author's instruction guidelines. These include *Biophysical Journal*, *FEBS*, *PNAS*, *Nature Publishing Group (NPG)*, *Public Library of Science (PLOS)*, *Royal Society of Chemistry (RSC)*, and *BioMed Central (BMC)*.

Model submission to BioModels Database is free and open to everyone. Models are accepted in two formats, SBML (Systems Biology Markup Language) (Hucka et al. 2003) and CellML (Lloyd et al. 2004). Once submitted, each model is assigned a unique and perennial identifier, which allows users to access and retrieve it. It then passes through a series of checking steps before it is published in BioModels Database (Fig. 1). Models are divided in two subbranches. Models in both subbranches are fully SBML compliant but differ in their curation status:

- (i) Curated models: Models that satisfy the MIRIAM (Minimum Information Required in the Annotation of Models) guidelines (Le Novère et al. 2005) progress to the curated branch. These models are thoroughly checked for standard compliance, correspondence with the reference publication and reproducibility of results.
- (ii) Non-curated models: Models can be in the non-curated branch for several reasons: non-MIRIAM-compliant models (e.g., they do not reproduce results published in the reference publication), pathway maps or models of networks, and models that provide insufficient quantitative results required for validation. This branch also temporarily includes models that have not yet been curated due to time or resource constraints.

Following curation and annotation (see section “Model Annotation” below), models are tagged as

BioModels Database: A Public Repository for Sharing Models of Biological Processes, Fig. 1 Production pipeline of the literature-based

models. This figure illustrates the sequence of steps that each model undergoes, from submission to publication

BioModels Database: A Public Repository for Sharing Models of Biological Processes, Fig. 2 Growth of BioModels Database. Number of models (blue) and number of variable relationships (green). The number of relationships includes SBML’s “reactions,” “rate rules,”

“assignment rules,” and “events.” There has been approximately a 20-fold increase in the number of models since the launch of the resource in 2005, with the average complexity of the models being increased five times during the same period

ready for publication and become available online with the following release of BioModels Database. Releases are scheduled two to four times a year.

Figure 2 shows the growth in number and size (complexity) of models, since its origin in 2005. Figure 3 shows the classification of curated models based on Gene Ontology

BioModels Database: A Public Repository for Sharing Models of Biological Processes, Fig. 3 Classification of models based on GO annotation of curated models

(GO) (Ashburner et al. 2000) terms present in the model annotation.

Certain simulation tools support only specific Levels or Versions of SBML. For this reason, BioModels Database provides models in alternative SBML versions, in addition to the version that was used by the curators to check the model. It also provides models in a variety of other formats such as BioPAX (<http://www.biopax.org/>), the Virtual Cell Markup Language (VCML) (<http://vcml.org/>), XPPAUT (<http://www.math.pitt.edu/~bard/xpp/xpp.html>), Scilab (<http://www.scilab.org/>), Octave (m-file) (<http://www.gnu.org/software/octave/>), and PDF (<http://www.ra.cs.uni-tuebingen.de/software/SBML2LaTeX>). Furthermore, the reaction network of the model encoded in the Systems Biology Graphical Notation (SBGN) (Le Novère et al. 2009) is available in PNG and SVG formats.

BioModels Database provides a basic online simulation using SOSlib (Machne et al. 2006). The simulation results are returned both in graphical and textual forms. An additional and more flexible simulation tool is available for many models using JWS Online. Some models are described in greater detail in the “Model of the Month.” This takes the form of a brief article discussing the biological background, significance, structure, and results of a particular

model. Another important feature provided for curated models is the ability to generate sub-models from a user-selected set of model elements. These sub-models can be downloaded in SBML and used, for instance, in the modular design of new models or to expand existing models.

B. Models Generated from Pathway Resources (Path2Models).

Driven by the growing number of biochemical pathways and reconstructions, the Path2Models project (Büchel 2013) targeted the conversion of pathway information initially from KEGG (Kanehisa and Goto 2000), BioCarta (Schaefer et al. 2009), MetaCyc (Karp et al. 2000), and SABIO-RK (Wittig et al. 2012) into standard-compliant computational models.

There are currently three major types of models in this branch:

- (i) Genome-scale metabolic reconstructions: These models are generated by extracting pathway data from the KEGG and MetaCyc databases and subjected to FBA.
- (ii) Quantitative, kinetic models of metabolic pathways: These models are generated based on the metabolic pathways distributed by KEGG described as processes, in combination with experimentally determined rate

laws and parameter values from the SABIO-RK database.

- (iii) Qualitative, logical models of non-metabolic (primarily signaling) pathways: These models are generated based on the non-metabolic pathways distributed by KEGG, with additional information from BioCarta pathways.

Model Annotation

In order to facilitate efficient search and enhance interpretability both by users and software tools, models are cross-linked with other database entries and terms from controlled vocabularies. Annotations are included in the models directly using [Identifiers.org](http://identifiers.org) URIs (Juty et al. 2012). Such annotations provide a consistent and perennial way to identify model components, and an anchor which may be used to merge, or expand the scope of models.

Model Search, Browse, and Retrieval

BioModels Database provides a complete list of models available for browsing. Curated models can also be browsed based on taxonomy or Gene Ontology (GO) terms used in their annotation. Users can also search and retrieve models of interest using the annotations and related information.

Web Services

BioModels Database provides web services (<http://www.ebi.ac.uk/biomodels-main/web-services>), allowing, for example, direct search and retrieval, and the creation of sub-models. A Web Services Description Language (WSDL) file enables software to understand available functions and their usage. The complete list of available methods, as well as a Java library and the associated documentation is provided on the BioModels Database website.

BioModels Database is developed under the GNU General Public License and the software is freely available from its SourceForge repository

(<http://www.ebi.ac.uk/biomodels-main/webservices>).

Biophysical Models of Calcium-Dependent Exocytosis

Victor Matveev
Department of Mathematical Sciences, New
Jersey Institute of Technology, Newark, NJ, USA

[Non-constitutive exocytosis](#) [exocytosis](#); [Regulated exocytosis](#)

Definition

Calcium-dependent exocytosis is the biochemically controlled fusion of the bilipid secretory

vesicle membrane with the bilipid cell membrane, triggered by the binding of several calcium ions (Ca^{2+}) to control proteins such as synaptotagmins anchored at the interface between these two membranes. Exocytosis results in the release of vesicle contents into the extracellular space, namely the release of neurotransmitter into the synaptic cleft in the case of neuronal synapses and neuromuscular junctions, or the secretion of hormone into the blood stream in the case of endocrine cells. Exocytosis also allows the transmembrane proteins contained in the vesicle membrane to be incorporated into the cell membrane, although such membrane protein trafficking is more characteristic of Ca^{2+} -independent, constitutive exocytosis.

Detailed Description

In synapses, neuromuscular junctions, and endocrine cells, exocytosis of a neurotransmitter or hormone-containing vesicle occurs through the interaction of the fast-binding isoforms of the Ca^{2+} -sensing protein synaptotagmin (namely Syt1, Syt2, and Syt9) with the molecules of the SNARE (soluble N-ethylmaleimide-sensitive factor attachment protein receptor) complex spanning the cell and vesicle membranes (Jahn and Fasshauer 2012; Moghadam and Jackson 2013). The main elements of the secretory channel-vesicle complex are schematically illustrated in Fig. 1. Despite their highly specialized morphology, a similar exocytosis triggering mechanism is found at most high-throughput ribbon sensory synapses (Cho and von Gersdorff 2012; Sterling and Matthews 2005), except for the cochlear hair cells. Those auditory synapses may differ in both the molecular exocytosis machinery and their Ca^{2+} sensitivity (Nouvian et al. 2011), and may involve nonneuronal isoforms of synaptotagmin (Johnson et al. 2010) or a distinct Ca^{2+} sensor, otoferlin (Michalski et al. 2017; Pangrsic et al. 2012; Roux et al. 2006). The mechanism of exocytosis of hormone-containing large dense-core vesicles in endocrine cells is very similar to the mechanisms of neurotransmitter vesicle release (Chow et al. 1992; Heinemann et al. 1994; Voets 2000), but typically proceeds at

B

Biophysical Models of Calcium-Dependent Exocytosis, Fig. 1 Secretory channel-vesicle release complex. The vesicle is shown in a fully docked state preceding fusion. The opening of a voltage-gated Ca^{2+} channel leads to the entry of Ca^{2+} ions (red circles) into the cell, resulting in a “domain” of elevated Ca^{2+} concentration, which can reach tens of μM close to the vesicle, some 20–30 nm away from the channel. The SNARE protein

complex (green polygon) interacts with synaptotagmin (magenta polygon) that serves as the fast Ca^{2+} -sensitive trigger of the vesicle-membrane fusion. Multiple SNARE complexes around the base of the vesicle are involved in exocytosis, only one of which is shown. At many synapses, the tight co-localization of Ca^{2+} channels and SNARE proteins is promoted by direct interactions between the relevant proteins (orange bar)

slower rates due to a somewhat different morphology of the release site, slower Ca^{2+} binding kinetics of the relevant synaptotagmin isoforms, and looser coupling between voltage-dependent Ca^{2+} channels and release-ready vesicles (Kasai 1999; Martin 2003; Moghadam and Jackson 2013; Verhage and Toonen 2007; Wu et al. 2009). It should be noted however that certain classes of endocrine cells such as pancreatic beta cells exhibit a close channel-vesicle coupling similar to that of neuronal synapses (Barg et al. 2001).

The dependence of the neurotransmitter or hormone release rate on Ca^{2+} concentration is known to be steeply nonlinear, as was first observed (Dodge and Rahamimoff 1967) when examining neuromuscular junction potentials at different extracellular Ca^{2+} concentrations, and later confirmed in studies that directly varied intracellular Ca^{2+} concentration using caged- Ca^{2+} release in endocrine cells, the giant calyx of Held synapse, and other synaptic terminals (Gentile and Stanley 2005; Neher and Sakaba 2008; Stanley 2016). For low, sub-saturating concentrations of Ca^{2+} , this nonlinear relationship can be summarized as:

$$R([Ca]) \propto [Ca]^n \quad (1)$$

Here $[Ca]$ denotes Ca^{2+} concentration at the vesicle fusion site, R denotes instantaneous neurotransmitter release rate, and n is the intrinsic (biochemical) Ca^{2+} cooperativity of exocytosis, which varies from 3–5 in most preparations. Note however that a significantly less cooperative, near-linear Ca^{2+} dependence has been reported in mature auditory hair cells, possibly because of differences in molecular exocytosis sensors mentioned above (Cho and von Gersdorff 2012; Johnson et al. 2010; Nouvian et al. 2011), although it has been suggested that the linear dependence could potentially arise from the averaging across synaptic contacts (Heil and Neubauer 2010).

The release (exocytosis) rate R is usually given in units of vesicles per second and measured as a membrane capacitance increase or by electrochemical detection of released molecules, using a carbon fiber electrode, but often assessed only indirectly by measuring postsynaptic currents or potentials. The steep nonlinear dependence given by Eq. (1) indicates that simultaneous binding of

several Ca^{2+} ions to synaptotagmin Ca^{2+} sensors is needed for release. In fact, the biochemical cooperativity provides a lower bound on the number of Ca^{2+} binding events required for exocytosis. Although the C2A and C2B domains of a given synaptotagmin molecule do possess a total of five Ca^{2+} ion-binding sites (Chapman 2002), not all of these sites are necessarily involved in fast (phasic) Ca^{2+} -triggered exocytosis. Therefore, it is likely that the relevant Ca^{2+} -binding sites are distributed among several synaptotagmin molecules, which dimerize and bind Ca^{2+} simultaneously to trigger vesicle fusion (Mutch et al. 2011). In fact, studies suggest that more than 10 synaptotagmin molecules typically associate with a single neurotransmitter vesicle (Takamori et al. 2006). However, in accordance with the above-mentioned Ca^{2+} cooperativity measurements, most models reviewed below assume about five Ca^{2+} -binding sites, all of which have to be occupied for vesicle fusion to occur. An alternative detailed model that assumes an excess of Ca^{2+} -binding sites and includes Monte-Carlo simulation of Ca^{2+} ion diffusion and binding have been examined (Dittrich et al. 2013; Luo et al. 2015b).

While the main characteristics of exocytosis outlined above are in general understood, and the molecular components of exocytosis have been identified, the precise sequence of molecular steps leading to exocytosis is still being debated, which explains the high degree of interest in biophysical models of this phenomenon. We also note that this process involves spatial scales of tens of nanometers, and sub-millisecond temporal resolution, well beyond the resolution of optical imaging methods, which underscores the important role of biophysical modeling in understanding exocytosis and in interpreting indirect measurements of its properties.

A complete biophysical model of secretory vesicle exocytosis requires specifying the following model components: (1) the morphology of the synaptic vesicle docking site, namely the spatial channel-vesicle arrangement; (2) the properties of endogenous Ca^{2+} buffers and other Ca^{2+} homeostasis mechanisms; (3) a method for simulating Ca^{2+} diffusion and buffering to endogenous Ca^{2+} buffers; and (4) a model of Ca^{2+} binding by the

synaptotagmin release sensors. Here we focus on the latter component of the model. Examples of comprehensive models of this process are given at the end of this entry.

Sequential Ca^{2+} -Binding Model

Assuming for concreteness five distinct Ca^{2+} -binding sites comprising the putative exocytosis gate (sensor) X , the most general Ca^{2+} -sensitive exocytosis process can be described by the following reaction (Heidelberger et al. 1994; Kasai 1999):

where $[Ca]$ is the Ca^{2+} concentration at the vesicle site, $k_j^\pm$ are the binding and unbinding rates of each binding site, and the final irreversible reaction represents the actual vesicle fusion event. In Eq. (2) and below, Ca^{2+} binding is indicated by a product between the relevant binding rate and the Ca^{2+} concentration variable, $[Ca]$. In a deterministic simulation, this reaction is converted to a system of ordinary differential equations, using the principle of mass action:

$$\begin{cases} \frac{d[X]}{dt} = -k_1^+[Ca][X] + k_1^-[CaX] \\ \dots \\ \frac{d[Ca_5X]}{dt} = k_5^+[Ca][Ca_4X] - (\gamma + k_5^-)[Ca_5X] \end{cases} \quad (3)$$

where $[Ca_nX]$ represents the fraction of exocytosis gates with n binding sites occupied by a Ca^{2+} ion. The fusion rate is given by the product $\gamma [Ca_5X]$. Note that the Ca^{2+} concentration, $[Ca]$, should be modeled independently; in the simplest case of global Ca^{2+} elevation produced by caged Ca^{2+} release, it is approximately constant. When modeling exocytosis triggered by action potentials, $[Ca]$ can be represented as a brief pulse of a certain width and amplitude; more detailed models of Ca^{2+} dynamics are reviewed below.

In Eqs. (2 and 3), the binding and unbinding rates $k_j^\pm$ are in general distinct, and if the earlier unbinding rates are slow, a significant accumulation of partially bound states $[Ca_nX]$ can result during a train of stimuli; such accumulation due to slow unbinding is the basis for the so-called bound- Ca^{2+} model of synaptic facilitation (Bertram et al. 1996; Matveev et al. 2006).

Parallel Ca^{2+} -Binding Model

It is instructive to first consider the simplest scenario where all five release sites comprising exocytosis gate X are identical and can bind Ca^{2+} independently, leading to the following simplified version of the reaction given by Eq. (2) (Kasai 1999; Voets 2000):

Here the final reaction representing vesicle fusion is irreversible and is triggered when all five binding sites are occupied; exocytosis proceeds at rate $r = \gamma [Ca_5X]$. Even though Eq. (4) appears to describe a series of five consecutive binding reactions, it is equivalent to five identical reactions occurring in parallel, with fusion taking place when all five sites are bound.

The following alternative version of the exocytosis model by Bollmann and Sakmann (2005) and Bollmann et al. (2000) partially decouples the vesicle pool variable undergoing release and the Ca^{2+} sensor state variables, and also postulates the existence of an independent final release-promoting conformational transition reaction occurring after the release sensor is fully Ca^{2+} bound:

Here V represents the vesicle pool undergoing fusion, with vesicle fusion rate given by the

product $\rho V[Ca_5X^*]$, where ρ is the maximal vesicle fusion rate. The inclusion of an additional post-binding step helps to achieve more constant shape of the release time course at different amplitudes of Ca^{2+} influx seen in experiments (Bollmann et al. 2000; Yamada and Zucker 1992). In (Bollmann et al. 2000) the parameter values that were found to fit well the data from the calyx of Held synaptic terminal are given by $\rho = 40 \text{ ms}^{-1}$, $k^+ = 0.3 \mu\text{M}^{-1} \text{ ms}^{-1}$, $k^- = 3 \text{ ms}^{-1}$, $\gamma = 30 \text{ ms}^{-1}$, $\delta = 8 \text{ ms}^{-1}$.

We note that most of the Ca^{2+} binding rates quoted in the literature are inferred from the studies on the calyx of Held synapse and other synapses that primarily involve the faster Syt2 isoform of synaptotagmin in its natural physiological environment. Other isoforms of synaptotagmin may have significantly different values of the Ca^{2+} binding and unbinding rates (Bornschein and Schmidt 2018; Moghdam and Jackson 2013). For example, the following model by Voets (2000) accurately predict exocytosis of the readily releasable pool of vesicles in chromaffin cells caused by the Ca^{2+} binding to synaptotagmin isoform Syt1:

where $k^+ = 4.4 \cdot 10^{-3} \mu\text{M}^{-1} \text{ ms}^{-1}$, $k^- = 0.056 \text{ ms}^{-1}$, and $\gamma = 1.45 \text{ ms}^{-1}$.

Cooperative Ca^{2+} -Binding Model

Some studies suggest that the Ca^{2+} -sensitive exocytosis triggers exhibit strong cooperativity, whereby the target protein undergoes a conformational change with each successive Ca^{2+} ion binding, which in turn leads to an increase in the Ca^{2+} affinity of the remaining (yet unoccupied) Ca^{2+} -binding sites. The following widely used modification of reaction given by Eq. (2) has been proposed to implement this possibility (Beutner et al. 2001; Felmy et al. 2003; Heidelberger et al. 1994; Kochubey et al. 2009;

Sakaba 2008; Schneggenburger and Neher 2000):

Note that cooperative binding can be represented as either a progressive increase in forward binding rates or decrease of backward rates; Eq. (7) corresponds to the latter possibility. The cooperativity parameter should satisfy $b < 1$, with a typical value used in the literature of 0.25, indicating that the final Ca^{2+} -binding reactions are only slowly reversible. In (Schneggenburger and Neher 2000; Wolfel and Schneggenburger 2003) quantifying the Ca^{2+} -dependence of vesicle release at the calyx of Held synaptic terminal, the following parameter values were obtained: $k^+ = 0.09 \mu M^{-1} ms^{-1}$, $k^- = 9.5 ms^{-1}$, $\gamma = 6 ms^{-1}$, and the cooperativity parameter $b = 0.25$.

We note that the use of the term “cooperativity” is ambiguous in the context of exocytosis mechanisms. Cooperativity may refer to the high number of Ca^{2+} -binding sites (as inferred from the log-log slope of the Ca^{2+} concentration-response curve given by Eq. (1)) or may indicate that the Ca^{2+} binding affinities of these sites are not equal but increase as the first sites become Ca^{2+} bound.

Models with Independent Sets of Ca^{2+} -Binding Sites

Several recent biophysically detailed models of exocytosis take into account the possibility that Ca^{2+} may bind to several different proteins or to different domains of the same protein, such as the C2A and C2B domains of synaptotagmin, each characterized by a distinct set of rates and cooperativity values. Examples of such models are given further below in the context of more comprehensive models of exocytosis – see model schemes (16 and 20).

Exocytosis Rate at a Steady Ca^{2+} Concentration

To understand the exocytosis rate during prolonged Ca^{2+} elevation, for instance, to reproduce caged- Ca^{2+} release experiments, it is of interest to consider the equilibrium point of the Ca^{2+} -binding reactions summarized above. Since all release models contain an irreversible transition to the fusion state, in the absence of endocytosis or vesicle refill from a reserve pool, the true equilibrium is achieved only when all vesicles are fused and release rate equals zero. Therefore, below we will assume a model with decoupled sensor binding state and vesicle pool state variables, as in Eq. (5), or consider a quasi-equilibrium in the case where resource depletion is small on the time scale of Ca^{2+} binding.

The equilibrium occupancy of a single first-order Ca^{2+} -binding reaction $Ca + X \rightleftharpoons CaX$ with forward rate k^+ and backward rate k^- is found by setting the rate of the first reaction in Eq. (3) to zero, which yields:

$$[CaX] = \frac{k^+[Ca]}{k^+[Ca] + k^-} = \frac{[Ca]}{[Ca] + K} \quad (8)$$

where the ratio of the backward and forward rates $K = k^-/k^+$ is referred to as the Ca^{2+} affinity or dissociation constant and is an important Ca^{2+} -sensitivity parameter: the lower the K , the higher is the affinity (sensitivity) of the release sensor. It follows from Eq. (8) that K represents the Ca^{2+} concentration at which half the sensors become bound. If the final fusion reaction requires the binding of all five sensors, in the absence of vesicle depletion, the release rate at equilibrium will be proportional to the fifth power of the steady-state binding occupancy given by Eq. (8):

$$R([Ca]) = \gamma \left(\frac{[Ca]}{[Ca] + K} \right)^5 \quad (9)$$

At low Ca^{2+} concentration, this agrees with the cooperativity condition given by Eq. (1). Note that the release rate equals $1/2^5$ of its maximal value when $[Ca^{2+}] = K$.

For the case of cooperative binding, Eq. (7), the steady-state fusion rate R in the absence of resource depletion ($\gamma \ll 1$) is

$$R([Ca]) = \frac{\gamma [Ca]^5}{[Ca]^5 + 5[Ca]^4 b^4 K + 10[Ca]^3 b^7 K^2 + 10[Ca]^2 b^9 K^3 + 5[Ca] b^{10} K^4 + b^{10} K^5} \quad (10)$$

where $[Ca]$ is the Ca^{2+} concentration at the release site. In the limit of very small values of b (strong cooperativity limit), the above expression approaches the well-known and widely used Hill function:

$$R([Ca]) \approx \gamma \frac{[Ca]^n}{[Ca]^n + K_D^n} \quad (11)$$

where $n = 5$ and $K_D \approx b^2 K$ ($b \ll 1$). The dissociation constant K_D quantifies the Ca^{2+} sensitivity of the entire five-step process, as opposed to the sensitivity of any individual Ca^{2+} -binding site: when $[Ca] = K_D = b^2 K$, the exocytosis rate reaches its half-maximal value. Note that this is the most constrained and most important model parameter, since extensive experimental data on Ca^{2+} sensitivity has been collected at various types of synaptic terminals. In general, physiological rates of release are found when $[Ca^{2+}]$ at the vesicle location reaches the range of 10–50 μM (Neher and Sakaba 2008), although there are reports that highly sensitive vesicle pools exist at some endocrine cells, possibly controlled by distinct isoforms of the synaptotagmin sensor with Ca^{2+} affinity of several μM (Pedersen and Sherman 2009).

Note that the Hill functional form given by Eq. (11) should only be viewed as a crude qualitative approximation of the true Ca^{2+} -dependence of exocytosis rate, even at equilibrium, and tends to be somewhat overused (Weiss 1997). This is because the agreement between Eqs. (10 and 11) becomes sufficiently accurate only for values of cooperativity parameter satisfying $b < 0.1$; in the absence of firm experimental evidence for such a strong cooperativity, the Hill function should be avoided. Assuming a more moderate but still strong cooperativity corresponding to the typically used value $b = 0.25$, fitting the data to a Hill function would lead to a gross underestimate

proportional to the equilibrium value of fully bound state Ca_5X , which yields (Weiss 1997):

of the true number of Ca^{2+} -binding sites, as illustrated in Fig. 2. This underestimate is mostly due to the poor match of the saturating part of the Hill curve and can be greatly improved by omitting the data from saturating levels of $[Ca^{2+}]$. Therefore, the most model-independent way of estimating the cooperativity factor n is to fit only the log-log slope of the experimentally obtained Ca^{2+} sensitivity curve below the saturation inflection, which is often done in practice.

Cumulative Release During Prolonged Ca^{2+} Elevation

The Ca^{2+} -dependence of release rate can be used to quantify the total cumulative release with prolonged Ca^{2+} elevation, as measured by the total membrane capacitance increase or the total amount of released neurotransmitter. In the case of prolonged and approximately steady Ca^{2+} elevation of duration Δt , the amount of fused vesicles is given by (Kasai 1999; Quastel et al. 1992):

$$F([Ca]) = F_{\max} [1 - \exp(-R_{eq}([Ca]) \Delta t)] \quad (12)$$

where $F_{\max}$ represents the total amount of available exocytosis resources (say, vesicles) and $R_{eq}([Ca])$ represents the equilibrium reaction rate at Ca^{2+} concentration $[Ca]$ attained at the vesicle location. We note once again that this analysis assumes that the vesicle depletion is decoupled from the sensor binding state, as in the model given by Eq. (5). The exponential term can be interpreted as the probability of release failure. For pulses raising $[Ca^{2+}]$ to sub-saturating levels, given Eq. (1), we have $R \approx k[Ca]^n$, therefore (Quastel et al. 1992):

Biophysical Models of Calcium-Dependent Exocytosis, Fig. 2 Hill-function fit underestimates true biochemical cooperativity and affinity of a fifth-order Ca^{2+} -binding reaction (Eqs. (7 and 10)), even in the case of moderately strong cooperativity parameter ($b = 0.25$). Note that the

low quality of the fit is mostly a result of poor matching of the saturating part of the curve by the Hill function: the cooperativity is more accurately predicted if only the non-saturating part of the data is considered (right panel)

$$F([Ca]) = F_{\max}[1 - \exp(-k[Ca]^n \Delta t)] \quad (13)$$

However, if $[\text{Ca}^{2+}]$ is high enough to saturate the release sensor during the long depolarizing pulse, the total amount of released neurotransmitter will become limited by the duration of stimulation only:

$$F = F_{\max}[1 - \exp(-R_{\max} \Delta t)] \quad (14)$$

As was explained above, Eqs. (12 and 13) only apply to the situation where $[\text{Ca}^{2+}]$ is elevated for a long time relative to the kinetics of the Ca^{2+} -binding sites, as for instance, during whole-cell $[\text{Ca}^{2+}]$ elevation produced by Ca^{2+} uncaging experiments. If on the other hand $[\text{Ca}^{2+}]$ is understood as the *peak* concentration achieved in the vicinity of the vesicle during a brief action potential, the above steady-state results would overestimate the true release and could only serve as an upper bound on release rate (Shahrezaei and Delaney 2005). The “true” neurotransmitter release rate would be given by a solution to the differential Eq. (5), with $[\text{Ca}^{2+}]$ representing the time-dependent Ca^{2+} concentration at the vesicle release site, which has to be modeled independently, using simulations of Ca^{2+} entry through Ca^{2+} channels, diffusion and binding to intracellular Ca^{2+} buffers.

Asynchronous Synaptic Transmission

Many synapses display a delayed phase of neurotransmitter release that persists after the stimulating presynaptic depolarization has ceased. This delayed component of exocytosis is termed asynchronous or delayed exocytosis, and at some synapses, it makes a significant contribution to the overall neurotransmitter release under physiological conditions (Rozov et al. 2019). There is continued debate whether the asynchronous component of synaptic transmission is a result of synaptic Ca^{2+} accumulation or whether it is caused by a distinct vesicle pool released via special mechanisms independent of the synchronous release component (Chung and Raingo 2013; Smith et al. 2012). The connection between delayed release and the so-called spontaneous release seen in the absence of stimulation is also not fully understood. Biophysical modeling is used extensively in testing different hypotheses about the mechanisms of asynchronous and spontaneous neurotransmitter release.

An intriguing feature of asynchronous release is that it seems to exhibit a lower, almost linear Ca^{2+} dependence (Kochubey and Schneggenburger 2011; Lou et al. 2005; Sun et al. 2007). The so-called allosteric model proposed by Lou et al.

(2005) explains the observed decrease in apparent cooperativity of Ca^{2+} action at low Ca^{2+} concentration by the presence of a slow conformational change of the release proteins, leading to a second

route of vesicle fusion, which becomes progressively less likely at higher Ca^{2+} concentration. This is implemented by the following scheme with a reverse-cooperativity parameter $f < 1$:

A more detailed model proposed by Sun et al. (2007) and referred to as the *dual sensor* model provides an improved quantitative description of release at low Ca^{2+} concentrations, since it reproduced more accurately the

latency of synaptic response at very low levels of Ca^{2+} . This model assumes two independent Ca^{2+} sensors acting in parallel and each triggering a distinct mode of neurotransmitter release:

Here the synchronous release involves a sensor “X” with Ca^{2+} -cooperativity of five, while a different and independent sensor “Y” is responsible for asynchronous release and possesses a cooperativity of two. Note that in this model implementation both sensors bind Ca^{2+} cooperatively, with equal cooperativity parameter b . The existence of two distinct sensors is supported by recent evidence that in some synapses asynchronous release is controlled by distinct Ca^{2+} -binding proteins. Among the candidates for such a specialized asynchronous release regulator are the

non-synaptotagmin sensor Doc2 (Yao et al. 2011), a distinct isoform of vesicle SNARE protein VAMP4 (Raingo et al. 2012), and the Syt7 isoform of synaptotagmin characterized by slow but high-affinity Ca^{2+} binding (Luo et al. 2015a; Turecek and Regehr 2018; Weber et al. 2014). An alternative possibility is that asynchronous release becomes prominent when the faster synaptotagmin isoforms like Syt1 are depleted, which removes their release-clamping influence (Turecek and Regehr 2019). However, as mentioned above, the mechanisms of asynchronous

as well as spontaneous release are still under debate and may well vary across synaptic types (Chung and Raingo 2013; Kaeser and Regehr 2014; Smith et al. 2012).

Multiple Vesicle Pool Models

Apart from the intrinsic heterogeneity in Ca^{2+} affinity and speed of exocytosis due to the existence of distinct release pathways guiding exocytosis of each vesicle, an additional explanation for the observed heterogeneous components of vesicle release is the existence of independent pools of vesicles with variable degree of “preparedness” for exocytosis. This heterogeneity is especially pronounced in endocrine cells, which exhibit a fast-decaying initial phase of release followed by a second, more slowly decaying component, but such behavior is also found in other high-throughput neuronal synapses such as the calyx of Held synaptic terminal and in ribbon synapses (Neher 2012; Neher and Sakaba 2008; Pedersen and Sherman 2009; Verhage and Toonen 2007; Voets 2000). The identity of such distinct vesicle pools is currently under debate: they could be distinguished either by the variations in the distance between vesicles and corresponding voltage-gated Ca^{2+} channels (“positional

priming”: (Wadel et al. 2007)) and/or by differences in the arrangement of the molecular machinery needed for exocytosis (“molecular priming” and “super-priming”: (Chung and Raingo 2013; Lee et al. 2013; Neher 2017; Sorensen 2004; Taschenberger et al. 2016; Verhage and Toonen 2007)).

Exocytosis models comprising multiple vesicle pools allow reproducing the observed heterogeneous release components. However, simple two-pool models comprising a readily releasable pool and a reserve pool of vesicles were already proposed in the earliest modeling studies of vesicle release, in order to account for the short-term depression of synaptic response arising from vesicle depletion (Elmqvist and Quastel 1965; Liley and North 1953; Neher 1998; Zucker and Regehr 2002).

Most quantitative models of exocytosis that include multiple releasable vesicle pools are based on the two-pool model of (Heinemann et al. (1993), Voets (2000), and Voets et al. (1999)) that was put forward to quantify two temporal components of secretory vesicle release in adrenal chromaffin cells. One implementation of such a two-pool model was explored by Sorensen (2004):

In this model, exocytosis proceeds with cooperativity value of three from both the slow (“sustained”) and fast synchronous pools, which are replenished via two

preparatory steps, docking and priming, from the reserve pool.

There are indications that in some cells, the slowly releasing pool may in fact have a much

higher sensitivity to Ca^{2+} , in the range of several μM rather than 10s of μM , which allows it to participate in exocytosis despite a much longer separation from the Ca^{2+} channels compared to the immediately releasable fast pool (reviewed in Pedersen and Sherman (2009)). The delay in the release of the highly sensitive vesicles is explained by the longer diffusional distance and therefore longer time required for Ca^{2+} concentration to reach μM range far from the Ca^{2+} channels. Such so-called highly Ca^{2+} sensitive pool (HCSP) has been described in adrenal chromaffin cells (Yang et al. 2002), rod photoreceptor ribbon synapses (Thoreson et al. 2004), and in insulin secreting beta cells (Yang and Gillis 2004). A recent multiple-pool model that includes the HCSP pool along with the lower-

affinity immediately releasable pool (IRP), and implements a deterministic bi-domain model of $[\text{Ca}^{2+}]$ dynamics, can be found in Pedersen and Sherman (2009). This model is based on an earlier model of Chen et al. (2008), and it accurately predicts the characteristic biphasic release of insulin from pancreatic beta cells. The first phase of secretion is mostly due to the docked vesicles that are rapidly recruited to the immediately releasable pool (IRP) and exocytosed in response to local “microdomain” $[\text{Ca}^{2+}]$ ($[\text{Ca}]_{\text{MD}}$) entering through L-type Ca^{2+} channels. In contrast, the second, delayed phase of insulin release builds up more slowly due to the recruitment of the reserve vesicles into the HCSP and gradual accumulation of cytosolic Ca^{2+} ($[\text{Ca}]_{\text{Cyt}}$) entering through R-type Ca^{2+} channels:

Here Ca^{2+} -dependent transitions are indicated in color, according to the primary source of Ca^{2+} for the corresponding transition. The R-type and L-type voltage-dependent Ca^{2+} channels (VDCCs) contribute respectively to the cytosolic and the microdomain pools of Ca^{2+} , $[\text{Ca}]_{\text{Cyt}}$ and $[\text{Ca}]_{\text{MD}}$ (the diffusional exchange between these two Ca^{2+} pools is not shown). The Ca^{2+} -dependent exocytosis steps lead to the two “fused” states, F_{HCSP} and F_{IRP} , which in turn feed into the final released insulin states R_{HCSP} and R_{IRP} through a final Ca^{2+} -independent pore-expansion transition.

Note that the existence of multiple vesicle pools can also serve as a potential explanation for asynchronous release reviewed above (Chung and Raingo 2013; Neher 2017). Another possibility is that the intrinsic sources of heterogeneity in release properties captured by the allosteric and the dual-sensor models (Eqs. (15 and 16)) are present in each vesicle (Kaesler and Regehr 2014; Sun et al. 2007). In particular, as reviewed above, in some synapses, asynchronous release may be mediated by specialized Ca^{2+} sensors. Further, both the synchronous and the delayed components are observed with global

(whole-terminal) Ca^{2+} elevations that activate vesicles in all pools. Therefore, both sources of heterogeneity, the ones intrinsic to each vesicle and the extrinsic ones (existence of distinct pools), may be relevant in many synapses (Kaesler and Regehr 2014). In order to take into account all factors of vesicle release heterogeneity and predict more accurately the exocytosis rate under low Ca^{2+} conditions, one can combine the dual-pool model with the allosteric model of Lou et al. (2005) or the dual-sensor model of Sun et al. (2007). This was done, for instance, by Wolfel and Schneggenburger (2003), who considered allosteric Ca^{2+} binding for both pools, as in Eq. (15) (neglecting however the exchange between the two pools due to the short time scales considered in that work). Finally, it should be noted that the separation of releasable vesicles into only two pools instead of a larger set of pools or a continuum of states is most probably a simplification, but this level of detail is sufficient to accurately quantify release under most physiological conditions (Neher 2017). Including more than two pools should be done with great care to avoid an underdetermined model and data over-fitting.

Models with Ca^{2+} -Dependent Vesicle Priming

Vesicle docking and priming steps in reactions 17 and 18 most likely include multiple molecular processes (involving Munc18 and other proteins) and morphological steps (e.g., positional priming), the identity and sequence of which are still under investigation (Lee et al. 2013; Verhage and Toonen 2007). Experimental evidence suggests that at least some of these

vesicle-priming steps are Ca^{2+} dependent in many synapses, albeit with a lower Ca^{2+} cooperativity compared to exocytosis itself, with a near-linear dependence on intracellular Ca^{2+} concentration (Neher and Sakaba 2008). Depending on the balance between the different vesicle pools at resting Ca^{2+} , the Ca^{2+} -dependent priming can manifest itself in two different properties of short-term synaptic plasticity (Zucker and Regehr 2002):

1. Under conditions of low initial release-ready vesicle pool size, Ca^{2+} -dependent priming would cause the secretion rate to increase during stimulation as a result of an increase in vesicle “mobilization” to the release-ready primed pool, which can serve as a mechanism of short-term synaptic facilitation (Dittman et al. 2000; Millar et al. 2005; Pan and Zucker 2009; Worden et al. 1997) (see also encyclopedia entry on ► “Facilitation, Biophysical Models”).
2. Under conditions of high vesicle release probability, Ca^{2+} -dependent priming would manifest itself through activity-dependent acceleration of recovery from short-term synaptic depression (Dittman and Regehr 1998; Hosoi et al. 2007; Stevens and Wesseling 1998; von Ruden and Neher 1993; Wang and Kaczmarek 1998).

The simplest model of release that includes a Ca^{2+} -dependent priming step can be obtained by modifying reaction 7: for instance, Millar et al. (2005) considered the following scheme (see also (Bornschein et al. 2013, Brachtendorf et al. 2015, Sakaba 2008) for a slightly modified version of this scheme):

The study of Millar et al. (2005) also considered a more detailed version of this model that takes into account the independence of Ca^{2+}

binding to C2A and C2B domains of synaptotagmin, leading to the following modification of above (see also (Pan and Zucker 2009)):

Here the horizontal state transitions represent the binding of the three C2A sites of synaptotagmin, while the vertical transitions correspond to the binding of the C2B sites, which is assumed to be independent of the Ca^{2+} binding of the C2A domain. Both domains are assumed to bind Ca^{2+} cooperatively (with cooperativity parameter $b_1 = b_2 = 0.5$). These models were successful in explaining the difference between release properties of the facilitating “tonic” and depressing “phasic” crustacean neuromuscular

junctions (Millar et al. 2005; Pan and Zucker 2009).

Vesicle priming has also been considered in the context of more detailed models that include multiple releasable vesicle pools. In such models, the priming step is usually assumed to occur upstream of the process of exchange between the slow-releasing and the fast-releasing vesicle pools. Adding the priming step to the scheme (17) leads to the following class of models (Verhage and Toonen 2007):

In this scheme, “super-priming” refers to the conversion of the slowly releasable pool to the fast releasable pool, the nature and the Ca^{2+} -dependence of which is currently unknown. Note that the use of the term “super-priming” is model-dependent; recently, it has been used to describe a newly identified additional kinetic

step in the priming of the fast pool at the calyx of Held synaptic terminal (Lee et al. 2013). The possible Ca^{2+} dependence of the conversion of the slow pool to the fast pool is unknown; it is possible that this conversion may even be retarded by Ca^{2+} at some synapses (Neher and Sakaba 2008). At the calyx of Held, the contribution of the fast

component of release is observed to increase with increasing Ca^{2+} levels, at the expense of the slow component (Wolfel et al. 2007). An explanation of this observation was suggested that the slow pool may be small at rest but increases due to activity-dependent conversion of vesicles from the fast pool, and that this conversion is less pronounced at high Ca^{2+} levels, so it is not able to reduce the fast pool at more intense stimulation levels (Neher and Sakaba 2008).

Spatially Resolved Exocytosis Models and the Vesicle-Channel Coupling

Models of Ca^{2+} binding by synaptotagmin sensors controlling the release of one or more vesicle pools are often combined with simplified models of intracellular Ca^{2+} dynamics that involve only one or two well-mixed spatial Ca^{2+} compartments. This level of detail is sufficient to simulate exocytosis in response to global elevations of Ca^{2+} produced by caged- Ca^{2+} compounds. However, deep understanding of physiological synaptic or endocrine transmission requires full three-dimensional simulation of intracellular Ca^{2+} diffusion and buffering. This in turn requires taking into account the latest data on the spatial arrangement of voltage-dependent Ca^{2+} channels and membrane-docked vesicles, which varies considerably across distinct cell types and stages of development (Bornschein and Schmidt 2018; Eggermann et al. 2012; Gentile and Stanley 2005; Matveev et al. 2011; Moser et al. 2006; Oheim et al. 2006; Stanley 2015, 2016; Walter et al. 2018). In fact, the heterogeneous release probability of secretory vesicles captured by the multiple vesicle pools models reviewed above can be a result of heterogeneous distance between vesicles and the presynaptic Ca^{2+} channels.

Since the geometric arrangement of vesicles and functional Ca^{2+} channels at the release sites is hard to probe using existing experimental techniques, testing the hypotheses on channel-vesicle distance has been one of the primary aims of the more comprehensive biophysical models of exocytosis. To simulate three-dimensional Ca^{2+}

dynamics, such detailed models use either stochastic simulation (Bennett et al. 2004; Ditttrich et al. 2013; Glavinovic and Rabie 2001; Ma et al. 2015; Nadkarni et al. 2012; Scimemi and Diamond 2012; Shahrezaei et al. 2006; Shahrezaei and Delaney 2005), deterministic solution of reaction-diffusion equations (Bohme et al. 2018; Bucurenciu et al. 2008; Gandasi et al. 2017; Matveev et al. 2009, 2011; Meinrenken et al. 2002, 2003; Schmidt et al. 2013; Weber et al. 2010; Zucker and Fogelson 1986), or steady-state approximations of Ca^{2+} distribution near an array of open Ca^{2+} channels (Bertram et al. 1999; Coggins and Zenisek 2009; Matveev 2016; Montefusco and Pedersen 2018).

Several particularly detailed modeling studies combine together many of the mechanisms reviewed above to build a comprehensive model of secretory vesicle exocytosis:

1. The model implemented in Ditttrich et al. (2013), Luo et al. (2015b), and Ma et al. (2015) is one of the most complete recent models of exocytosis that includes stochastic simulations of Ca^{2+} ions diffusion, buffering and binding to synaptotagmin sensors, taking into account the copy number of synaptotagmin molecules and SNARE complexes per vesicle (Chapman 2002; Han et al. 2004; Mutch et al. 2011). This is the first modeling study that considered the possibility that only a subset of synaptotagmin sites have to be Ca^{2+} -bound to trigger exocytosis, and Ditttrich et al. (2013) examines the effective Ca^{2+} cooperativity of exocytosis as an emergent characteristic of such partial binding of a subset of Ca^{2+} sensors.
2. The study of Pan and Zucker (2009) builds a comprehensive model of release and short-term plasticity at tonic and phasic crustacean neuromuscular junctions, based on Eq. (20) above, but adds positional priming, leading to a transition scheme describing vesicle exchange between the following distinct vesicle pools: reserve, docked, primed channel-detached, and primed channel-attached. One of the main aims of this study was to build a model that most fully accounts for the properties of short-term synaptic facilitation

observed at crustacean tonic neuromuscular junctions, as well as the properties of short-term depression and asynchronous release at phasic neuromuscular junctions.

These models are just two representatives of a class of comprehensive models of Ca^{2+} -dependent exocytosis that go beyond the simulation of vesicle release in response to a single presynaptic depolarization, aiming to reproduce short-term changes in synaptic transmission strength in response to prolonged or repeated stimulation. Such modeling work is reviewed in more detail in the entry ► [“Facilitation, Biophysical Models”](#).

Biophysical Models of Olfactory Mitral and Granule Cells

Guoshi Li

Department of Psychology, Cornell University, Ithaca, NY, USA

Definition

Biophysical models of olfactory mitral and granule cells are conductance-based compartmental models based on the morphological and electrophysiological properties of mitral and granule cells. Each cellular model incorporates a number of interconnected sections that represent physical cellular elements such as the soma, axon, dendrites, and/or specialized compartments such as spines. Each section, in turn, consists of one or more isopotential compartments, each of which contains passive and active ionic channels along with other mechanisms such as calcium buffering, typically modeled using the Hodgkin-Huxley formalism (Hodgkin and Huxley 1952). The parameters of these coupled equations are then adjusted to reproduce the salient membrane properties of mitral and granule cells. These biophysical models serve as an important tool to understand

information processing within the olfactory bulb (OB) quantitatively.

Detailed Description

Morphological and Electrophysiological Properties of Mitral Cells

Mitral cells (MCs) in OB have several salient morphological characteristics (Shepherd and Greer 1998). The cell body sends out a single primary (apical) dendrite and several secondary (lateral) dendrites. The primary dendrite extends several hundred micrometers and arborizes in a complex tuft within a glomerulus, while lateral dendrites are widely distributed in the external plexiform layer (EPL). The input resistance ranges from 88 to 280 M Ω , and the mean resting potential is about -63 mV (Desmaisons et al. 1999; Cang and Isaacson 2003). In response to depolarizing current pulses, MCs generate clusters of action potentials interspersed with long period of subthreshold oscillations (STOs) (Chen and Shepherd 1997; Desmaisons et al. 1999; Balu et al. 2004). Inhibitory postsynaptic potentials (IPSPs) reset the phase

of the STOs and also can generate rebound action potentials (Desmaisons et al. 1999).

Development of a Biophysical MC Model: An Example

Based on the morphology of mitral cells, a reduced, oligocompartmental MC model could consist of four sections: a soma, an apical dendrite, a lateral dendrite, and a glomerular tuft at the distal end of the apical dendrite (Fig. 1a). Each section is modeled as a cylinder whose dimensions are based on morphological measurements from mitral cells; reasonable examples are shown in Table 1 (Li and Cleland 2013). The long apical and lateral dendrite sections can be further divided into multiple compartments to more accurately model cable properties (individual compartments are by definition isopotential). For example, in the Li and Cleland model (Li and Cleland 2013), the apical dendrite comprises five compartments, and the lateral dendrite comprises seven compartments, whereas the electrotonically compact soma comprises a single compartment.

Generally, each compartment contains a passive leakage current and a number of active ionic

Biophysical Models of Olfactory Mitral and Granule Cells, Fig. 1 Compartmental model of a mitral cell (MC, Li and Cleland 2013). (a), Schematic representation of the MC model with distribution of active ionic conductances in each of its four sections. (b), Equivalent electrical circuit

of two identical interconnected neural compartments used to simulate MC cell excitability. Subscripts c1..ci denote i different active (variable) conductances and their associated reversal potentials (G_{Na}, G_K, etc., with reversal potentials E_{Na}, E_K, etc.).

Apical dend	3.5	370				
Tuft	0.5	20				
Lateral dend	3.4	500				

currents (Fig. 1a, compartments within a section have identical currents). The Li and Cleland model contains seven active currents: fast, spike-generating (I_{Na}), and persistent (I_{NaP}) sodium currents; a potassium delayed rectifier I_{DR} ; two transient potassium currents (fast-inactivating I_{A} and slow-inactivating I_{KS}); an L-type high-voltage-activated calcium current (I_{CaL}); and a Ca^{2+} -dependent potassium current I_{KCa} , based on previous experimental and modeling studies (Bhalla and Bower 1993; Wang et al. 1996; Desmaisons et al. 1999; Davison et al. 2000; Balu et al. 2004; Rubin and Cleland 2006; Balu and Strowbridge 2007). Figure 1b shows the equivalent electrical circuit of two basic neural compartments connected with an axial resistance R_a . Each compartment has a membrane capacitance C_m , a fixed membrane resistance R_m , and an equilibrium potential E_m associated with the ohmic leakage current that flows across R_m (values shown in Table 1 for the Li and Cleland model).

All ionic conductance kinetics in this model are modeled using the Hodgkin-Huxley formalism (Hodgkin and Huxley 1952). Specifically, the conductance for channel i , G_{ci} , is modeled as:

$$G_{ci} = g_{ci} m^p h^q \quad (1)$$

where g_{ci} is its maximal conductance density, m its activation variable (with exponent p), and h its inactivation variable (with exponent q). The kinetic equation for the gating variable x (m or h) satisfies a first-order kinetic model,

$$\frac{dx}{dt} = \phi_x \frac{x_{\infty}(V) - x}{\tau_x(V)} \quad (2)$$

where ϕ_x is a temperature-dependent factor, $x_{\infty}(V)$ is the voltage-dependent steady state, and

$\tau_x(V)$ is the voltage-dependent time constant. Equivalently, Eq. 2 can be written as:

$$\frac{dx}{dt} = \phi_x (\alpha_x(V)(1 - x) - \beta_x(V)x) \quad (3)$$

where $\alpha_x(V)$ and $\beta_x(V)$ are the voltage-dependent rate constants. The parameter values for the rate constants α_x and β_x , steady state x_{∞} , and time constant τ_x of the gating variables determine the model's dynamical properties and are typically based on electrophysiological measurements of mitral cells (e.g., voltage clamp or current clamp). The excitability of a segment of MC cell membrane modeled by a compartment of the type depicted in Fig. 1b can then be described by the following equation:

$$C_m \frac{dV_m}{dt} = \frac{(E_m - V_m)}{R_m} + \sum_i G_{ci}(E_{ci} - V_m) + \frac{(V'_m - V_m)}{R_a} + \frac{(V''_m - V_m)}{R_a} \quad (4)$$

where V'_m and V''_m are the voltages of the two adjacent compartments. Solving many coupled equations of the form in Eq. 4, with appropriate parameters, will generate the dynamical behavior of a mitral cell. Fortunately, specialized neuronal simulators such as NEURON (Carnevale and Hines 2006) and GENESIS (Bower and Beeman 2003) have made the implementation and numerical simulation of biophysical models easy and straightforward.

After implementation of the model, the next step is to select suitable parameters, so the model reasonably reproduces the experimental data from a particular cell type of interest. This usually involves adapting parameter values from previous literature, estimating or inferring them from

experimental data, and finally performing a parameterization and fitting procedure. Parameterization can be performed via exhaustive searching (brute force), supervised trial and error, and/or any of a number of more advanced, automated parameterization techniques. The Li and Cleland model, after parameterization, reproduces the experimentally observed activation patterns of mitral cells such as delayed first spike, clusters of action potentials interspersed with subthreshold oscillations (STOs), STO phase reset, and rebound spikes generated by IPSPs (Li and Cleland 2013).

Other Biophysical MC Models

A number of biophysical MC models incorporating different levels of detail and complexity have been developed (Bhalla and Bower 1993; Shen et al. 1999; Davison et al. 2000; Migliore et al. 2005; Bathellier et al. 2006; Rubin and Cleland 2006; Inoue and Strowbridge 2008). The model developed by Bhalla and Bower is a detailed, 286-compartment model based on intracellular recordings and morphological measurements. It aimed to study the details of single-cell morphology and channel distribution in cellular information processing. This complex model was reduced to two-, three- and four-compartment models by Davison et al. (2000) for computational efficiency in larger networks (Davison et al. 2003). Neither model implemented STOs or intermittent cluster firing patterns, however, which are important membrane characteristics of MCs (Desmaisons et al. 1999; Balu et al. 2004); consequently, Rubin and Cleland (2006) adapted the four-compartment Davison model to replicate these dynamical properties by adding additional current mechanisms as described by Desmaisons et al. (1999). The Shen et al. (1999) and Migliore et al. (2005) models are detailed, multi-compartmental biophysical models, but, as they sought only to study action potential generation and inter-glomerular synaptic transmission, they included only the fast sodium and delayed potassium channels. Bathellier et al. (2006) developed a single-

compartment model with five core currents capable of reproducing the essential firing properties of MCs for implementation of an oscillatory network. This single-compartment model was very efficient in network simulation, although at the price of neglecting the signal interactions between the soma and the dendrites (e.g., forward and back propagation). The model by Inoue and Strowbridge (2008) comprised two compartments (a soma and a dendrite) and utilized reduced current mechanisms in order to study persistent activity in OB. Thus, biophysical models of MCs can vary substantially in implementational details depending on the investigators' particular goals.

Morphological and Electrophysiological Properties of Granule Cell

Granule cells (GCs) differ from mitral cells – e.g., very different morphologies, channel components, and kinetics – and consequently are modeled differently. GCs have a soma (~8 μm diameter), which connects to a number of basal dendrites in the vicinity of the cell body, and several thin (approximately 1–2 μm), long (up to about 600 μm) radial dendrites projecting to the EPL, where they contact mitral/tufted cell secondary dendrites via large dendritic spines (Egger et al. 2003; Pinato and Midtgaard 2003). Two prominent features of GCs are their extremely high input resistances and Na^+ spike thresholds. Depending on the species, the input resistance ranges from 0.5 to 2 $\text{G}\Omega$, and the spike threshold is about –28 mV (Egger et al. 2003; Pinato and Midtgaard 2003; Pressler and Strowbridge 2006). The resting potential is about –65 mV for rats (Cang and Isaacson 2003; Pressler and Strowbridge 2006), and the membrane time constant is about 50 ms (Pinato and Midtgaard 2003). In response to positive current injection, GCs fire a short burst of Na spikes with a gradual attenuation of spike amplitude and slowly activating “ramping” depolarization often terminating in a sustained plateau near –20 mV (Wellis and Kauer 1994; Hall and Delaney 2002; Egger et al. 2003; Pinato and Midtgaard 2003). Biophysical models

of granule cells should replicate these basic properties.

Development of a Biophysical GC Model: An Example

A simple yet functional oligocompartmental GC model can consist of a soma and a radial dendrite connected to a spine shaft and body (Fig. 2; Li and Cleland 2013). Omitting detailed simulations of multiple spines, for example, this model was built for efficient integration of synaptic inputs from MCs in a network model. Its morphological parameter values and passive electrical properties are shown in Table 2. The GC model cell contains the following eight active ionic currents: a fast, spike-generating sodium current I_{Na} ; a potassium delayed rectifier I_{DR} ; a transient A-type potassium current I_A ; a noninactivating muscarinic potassium current I_M ; a low-threshold inactivating (I_{CaT}) and a high-threshold ($I_{CaP/N}$) calcium currents; a Ca^{2+} -activated nonspecific cation current I_{CAN} , and a Ca^{2+} -dependent potassium current I_{KCa} (Li and Cleland 2013). The GC is modeled as an equivalent electrical circuit of connected compartments as described above for the MC.

After parameterization, the Li and Cleland model reproduced the experimentally observed salient properties of GCs, including delayed first spike generation, ramping depolarization, and muscarinic neuromodulatory effects including the conversion of afterhyperpolarizations (AHPs) into afterdepolarizations (ADPs) and conditional persistent firing (Li and Cleland 2013). This type of model enables the direct association of channel properties with cellular responses. For example, the initial spike delay is caused by an “A”-type potassium current I_A , whereas blocking the I_M and I_{KCa} currents abolishes AHPs, thereby revealing latent ADPs mediated by the nonspecific cation current I_{CAN} (Pressler et al. 2007).

Other Biophysical GC Models

Several other biophysical GC models have been developed, exhibiting different levels of details and complexity (Bhalla and Bower 1993; Davison 2001; Inoue and Strowbridge 2008; Migliore and Shepherd 2008). The model developed by Bhalla and Bower is a detailed, 944-compartment model based on intracellular recordings and

Biophysical Models of Olfactory Mitral and Granule Cells, Fig. 2 Schematic representation of the Li and Cleland GC model with distribution of active ionic

currents. The spine compartments have the same ionic currents as the radial dendrite

Biophysical Models of Olfactory Mitral and Granule Cells, Table 2 Morphological parameter values and passive electrical properties of a GC model (Li and Cleland 2013)

Spine body	1	1				

morphological measurements. That complex model was reduced by Davison (2001) to a three-compartment model that exhibited most of the original model's physiological properties and was later implemented in a network simulation (Davison et al. 2003). A separate GC model developed by Migliore and Shepherd (2008) contained a soma, a main radial dendrite, and three second-order dendrites representing the medial and distal dendritic tree. This model only included three conductances (Na , K_{DR} , K_{A}), omitting all Ca^{2+} and Ca^{2+} -dependent currents. To investigate persistent firing properties in GCs, Inoue and Strowbridge (2008) developed a two-compartment GC model containing low- and high-threshold Ca^{2+} currents, a Ca^{2+} -dependent nonselective cation current, a sodium current, and two potassium currents. The model was able to reproduce Ca^{2+} spikes and Ca^{2+} - and voltage-dependent ADP responses as observed experimentally. It also suggested that persistent spiking in granule cells results from the interaction between a voltage-dependent after depolarization and a low-threshold Ca^{2+} spike.

Summary

Biophysical models of olfactory mitral and granule cells are conductance-based compartmental models constrained by the specific morphological and electrophysiological properties of mitral and granule cells. The general procedures for building such models include three steps: (1) represent the cell morphology with interconnected isopotential compartments, (2) decide upon appropriate ionic channels in each compartment based on their physiological properties, and (3) select suitable parameters so the model exhibits patterns of activity that correspond to experimental data. Depending on the particular goals of interest, different biophysical mitral and granule cell models incorporating different levels of detail and complexity have been developed. These biophysical models serve as important tools to integrate and interpret experimental data and to formulate quantitative working hypotheses concerning olfactory bulb function.

Forward-generative models of functional neuroimaging data

Definition

Forward-generative models are considered crucial to interpret and integrate data obtained with different functional neuroimaging modalities (Riera 2014). Typically, these models are formulated to represent biological principles at the mesoscopic scale, which basically stand for an average voxel (1 mm^3) in any brain imaging technique. To this end, biophysical models for neuronal activity, which are mostly available from the *neuronal computation* community, have been modified to incorporate general physiological mechanisms governing glial cell activity, vascular dynamics, and metabolism. For the cerebral cortex, the most relevant brain structure in functional neuroimaging, a variety of such extended biophysical models has been consolidating around three main research topics over the last decade: (a) the principles for neurovascular coupling, (b) the organization of cortical microcircuits, and (c) the cellular metabolism with emphasis on the nerve-ending particles. After modeling from mesoscopic variables to neuroimaging data, inversion of generative models provides insight into these underlying mechanisms of brain function and cognition.

Detailed Description

Neuroimaging data constitute different reflections, governed by basic principles in physics, of a common cause originated from the activity of connected cellular networks. Therefore, formulating biophysical models that embrace both the underlying causal phenomena and the observational principles is essential for (Stephan et al. 2006):

- (a) Performing statistical inference about the cellular states, exogenous inputs, and network topology.
- (b) Combining different modalities of functional neuroimaging data.

The state-space formalism constitutes one of the most general forms for representing these models. In this formalism, a state-space equation

is used to describe the evolution of the cellular activity, and an observation equation specifies how these hidden (cellular) states $x(\vec{r}, t)$ produce discrete neuroimaging data y_{t_k} .

The state equation:

$$x(\vec{r}, t) = f(x(\vec{r}, \tau \in [t - \tau, t]), i(\vec{r}, t), \Theta(\vec{r})) \quad (1)$$

$$\text{The states } x(\vec{r}, t) = (x_1(\vec{r}, t), x_2(\vec{r}, t), \dots, x_N(\vec{r}, t))$$

are represented by an N-dimensional vector field that dynamically evolves on time as described by Eq. 1. An exogenous multivariate input $i(\vec{r}, t)$ is assumed to perturb the system at each time instant. In principle, this input could include both deterministic $u(\vec{r}, t)$ and stochastic $\xi(\vec{r}, t)$ components. A vector field $\Theta(\vec{r})$ is included to represent important physiological parameters of the neuronal network (e.g., synaptic strength, metabolic rate, vascular reactivity). In general, the state vector $x(\vec{r}, t)$ depends through the function f in Eq. 1 on its present/ τ -past values. Note that since neuronal networks are intrinsically autonomous systems, the dependency with time is exclusively by way of the exogenous input.

The observation equation:

$$y_{t_k} = g(x(\vec{r}, t_k)) + \varepsilon_{t_k} \quad (2)$$

The data vector y_{t_k} comprises neuroimaging observations $\{y_{t_k}^{l,m}\}$ from different locations (subscript l) and modalities (superscript m). Function g in Eq. 2 does not depend explicitly on time. The detailed form of this function for each particular modality could be found in Toga and Mazziotta (2002). They may depend on instrument characteristics, sensor specificities, and experimental conditions. An independent multivariate white noise ε_{t_k} is typically added to the observations. Figure 1 summarizes cause-effect mechanisms and mesoscopic states underlying biophysical models in neuroimaging as well as typical observation modalities and techniques.

The state Eq. 1 is written in a general form. There are two relevant cases that are of interest.

Discrete Nonparametric Models

$$X_{t_k}^l = f_l\left(\left\{X_{t_k-k}^l, k' = 0, \dots, N_l\right\}, u_{t_k}^l, \Theta_l\right) + \xi_{t_k}^l \quad (3a)$$

This constitutes a type of multivariable autoregressive (MAR) model, which is useful to characterize discrete cellular state dynamics. For each voxel, the system comprises a deterministic and time-varying external input $u_{t_k}^l$ as well as a vector of parameter Θ_l . In this particular case, the system noise is represented by a multivariate white noise $\xi_{t_k}^l(0, \sum_{t_k}^l)$. When $\sum_{t_k}^l$ varies with time, it represents a heteroscedastic state-space model for non-stationary time series. Compartmental GARCH models are very useful for dynamic nonstationary signal decomposition. For neuroimaging, time series can be assumed in general stationary ($\sum_{t_k}^l = \sum^l$). Function f_l can be represented by the Hammerstein, ExpAR, and RBF-AR models for nonlinear dynamics. An innovation-based approach is typically used for the characterization of nonlinear and/or non-Gaussian time series. This approach is combined with maximum likelihood criteria to define proper statistical identification methods. Hidden cellular states can be estimated using Kalman and extended Kalman filtering techniques. There exist useful empirical (e.g., bootstrap, cross-validation, Jackknife) and theoretical (Akaike information criteria “AIC,” Bayesian information criteria “BIC”) criteria for model selection. We can use some version of Granger causal modeling (i.e., *Wiener-Akaike-Granger-Schweder influence*, *WAGS causality*) to study the topology of the cellular networks. Although discrete nonparametric models are not formulated on pure biological assumptions, they are very useful to explore specific hypotheses about working principles of cellular networks and accordingly narrow the family of plausible biophysical models. The following literature is recommended for details about this particular type of state-space models (Ozaki 2012, 2014; Valdes-Sosa et al. 2011; Stephan and Roebroeck 2012). This type of model has been extendedly used to describe EEG/MEG and fMRI data.

Biophysical Models: Neurovascular Coupling, Cortical Microcircuits, and Metabolism, Fig. 1 Cause-effect relationship between the cellular states and actual observations. A particular inducing event will trigger neuronal (i.e., action potential “AP,” postsynaptic potential “PSP”) and astrocytic (i.e., calcium signaling) activities. These activities will cause three major responses: (a) a flow of ionic currents across the cortical microcircuits, (b) the metabolizing of oxygen and glucose to build the required energy substrates, and (c) the functional hyperemic response necessary for new supplies and residual cleaning. The ionic currents will create volumetric current source densities (vCSD) within a voxel of interest. Changes in the d-glucose concentration (*Gluc*) and the oxygen partial pressure (*pO₂*) will result from the metabolism of these two molecules. A reduction in the cerebral vascular resistance (CVR) constitutes the primary effect of the functional

hyperemic response. The final mesoscopic variables are as follows: the primary current density (*PCD*), the cerebral metabolic rate of oxygen (*CMRO₂*), the deoxyhemoglobin (*dHb*), the cerebral blood flow (*CBF*), and the cerebral blood volume (*CBV*). There are constitutive relationships between some of these mesoscopic variables. They are either directly or indirectly reconstructed from functional neuroimaging (e.g., EEG/MEG, PET/SPECT, NIRS, and MRI) by a variety of techniques, e.g., current source imaging (*CSI*); 99 mTc hexamethylpropyleneamine oxime (^{99m}Tc-HMPAO) by SPECT; fluorodeoxyglucose (*FDG*) and ¹⁵O₂ by PET; the differential path-length factor (*DPF*) method by NIRS; calibrated fMRI, blood-oxygen-level dependent (*BOLD*) signal, arterial spin labeling (*ASL*), ¹³C MRS, and ¹⁷O₂ by MRI

A model by Riera et al. (2005) constitutes one of the most representative examples of using a discrete nonparametric model for the combination of both multimodal neuroimaging and the statistical inference about network dynamics/topology.

Continuous Parametric Models

$$dX^l(t) = f_l(X^l(t), u^l(t), \Theta_l)dt + G^l dw^l(t) \quad (3b)$$

This constitutes a stochastic differential equation (SDE), which is useful to represent cellular

states with a continuous dynamics. Eq. 3b can be used to represent the states of single cells in a population, which are affected by a deterministic external input $u^l(t)$ and a stochastic thermal noise $w^l(t)$ (i.e., Wiener process, $E[w^l(t + \tau), w^l(t)] = 2D\delta(\tau)\delta_{ll}$ for each voxel. A vector Θ_l is also included to represent biologically meaningful parameters. While dealing with large amount of interacting cells, theoretical frameworks for assemblies are very useful (summary in Fig. 2). Among them, the Fokker–Planck equation for populations of cells having a diffusion model

**Biophysical Models:
Neurovascular Coupling,
Cortical Microcircuits,
and Metabolism,**

Fig. 2 Theoretical frameworks for assemblies of interacting cells

of interactions constitutes one of the most attractive. The Fokker–Planck equation describes the time evolution of the probability density function $p_I(x^I, t)$ of the cellular states $x^I(t)$ that follow the SDEs Eq. 3b.

$$\begin{aligned} \frac{dp_I(x^I, t)}{dt} = & -\nabla \cdot (f_I(x^I(t), u^I(t), \Theta_I)p_I(x^I, t))dt \\ & + \frac{1}{2} \sum_{ij} \frac{\partial^2}{\partial x_i \partial x_j} (H_{ij}^I p_I(x^I, t)) \end{aligned} \quad (4)$$

with $H^I = 2G^I D G^{I^T}$.

Equation 4 is also known as the Kolmogorov forward equation. It is assumed that the sample trajectories of the particle are continuous functions of time. However, they are nowhere differentiable with respect to time. The high dimensionality of the Fokker–Planck equation can be reduced by using the mean-field approximation, $p_I(x^I, t) = \prod_k p_k^I(x_k^I, t)$. The resulting low-dimensional Fokker–Planck equations describe the evolution of separable ensembles that are coupled by mean-field effects. These ensembles could represent different neuronal populations of a cortical minicolumn, e.g., layer II/III (or V) pyramidal cells (PCs), spiny stellate cells, and GABAergic interneurons. For example, the mean firing rate of large basket GABAergic

interneurons could be used as a postsynaptic-driven force to each individual layer II/III PC. However, these ensembles could also represent different types of cells (e.g., neurons and astrocytes). For example, the mean firing rate of a particular population of nitrgergic GABAergic interneurons could be the driven vasodilative force acting on individual smooth muscle cells at the same cortical area. In other words, by coupling the ensembles through the mean-field approach the flow in the phase space of one ensemble is $\Gamma_I^k(x_k^I(t), \{\mu_k^I(t), \forall_{k' \neq k}\}, u^I(t), \Theta_I)$, with the means $\mu_k^I(t) = E[x_k^I(t)]$. In the SDE representation, the mean-field approach is equivalent to a system of coupled SDEs. Still, the main problem with both approaches is to create efficient methods to integrate respective differential equation systems, which have in principle a high dimensionality. Circumnavigating the problem of integrating high-dimensional Fokker–Planck equation systems for the density in state-space models defined by coupled SDEs is not a new topic. There are two main methods for solving this problem. One of them is based on the assumption of Gaussianity for densities $p_I(x^I, t)$ (i.e., the Laplace assumption). Therefore, it focuses on obtaining ordinary differential equations for the first two moments (i.e., means and variances) of the state variables (Marreiros et al. 2008). However, the most popular method is based on the so-called weak integrators for SDEs. The weak

methods allow the computation of any smooth functional on the state variables, where the moments are particular cases. Several methods have been proposed for weak integration of stochastic differential equations (Kloeden and Platen 1999). Continuous parametric models with delays have been solved in the past for neuroimaging data by transforming them into systems of SDEs and algebraic equations. The following literature is recommended for details about this particular type of state-space models (Deco et al. 2008; Deco 2014; Valdes-Sosa et al. 2011). The dynamic causal modeling (DCM, Friston et al. 2003; Stephan et al. 2007; Daunizeau et al. 2011) constitutes the most established type of continuous parametric models with variants in almost of blue-highlighted levels in Fig. 2. The DCM formalism has been extensively used to obtain connectionist diagrams (i.e., effective connectivity) between neuronal populations in different brain locations from neuroimaging data. Different variants of the local linearization (LL, Ozaki 2012) method have been applied to EEG and fMRI data covering all yellow-highlighted levels in Fig. 2.

Neuronal Mass Models

The so-called neuronal mass models result from particular approximations either from the mean-field models (no diffusion) or from the coupled mean-field models through the method of moments (non-curved). In general, for the neuronal mass models, the full ensemble density is replaced by a center of mass at a particular point. Then, a dynamic equation is used to describe the evolution of this center of mass with time. The neural-field models are an important generalization of the neural-mass models by allowing for states to be functionals of position on the cortical sheet. This type of model cannot be defined as particular case of general Eq. 1. A general discussion about these two types of models can be found in Deco et al. (2008).

General mesoscopic states: PCD, $\vec{J}_P$; CMR_{O_2} , cMR_{O_2} ; CMR_{Glc} , cMR_{glc} ; dHb, q ; CBF, f ; CBV, v .

Examples of Relationships between Mesoscopic Variables

In general, these mesoscopic states can be represented by some of the abovementioned coarse-grained versions of Eq. 1. Biophysical generative models with balanced excitatory and inhibitory neuronal populations with specific oxygen-to-glucose indexes (OGI) have been systematically introduced to establish relationships between $\vec{J}_P$ and metabolic/hemodynamic variables. Some of these models link $\vec{J}_P$ with instantaneous (ensemble average) postsynaptic membrane depolarizations and/or presynaptic firing rates of neurons. The nonlinear balloon model was introduced to relate states q , f , and v , which was inspired by the **Windkessel theory** for the *flow–volume relationship* and the **oxygen limitation assumption**. Oxygen transport models are combined with **mass-balance equations** to establish relationships between cMR_{O_2} , f , and q , through some internal states such as the intra-/extravascular oxygen contents and the blood oxygen saturation fraction. In some models, neuronal demand of oxygen is defined by complex dependencies in the oxygen extraction fraction (OEF). Compartmental models for plasma and tissue (with both phosphorylated and dephosphorylated Glc) have been employed to describe the relative changes in cMR_{glc} and v .

In order to understand the origin of the relationships between mesoscopic variables in the neocortex, three main biological mechanisms must be studied in detail: (a) the neurovascular coupling, (b) the cortical microcircuits, and (c) the cellular metabolism.

Neurovascular Coupling

Functional Hyperemia

The cerebral circulatory system is endowed with assorted vascular controlling mechanisms to facilitate the desirable cerebral perfusion in any particular brain area at a given time. Surface vessels in the brain are richly innervated at strategic positions by both sympathetic and parasympathetic nerves, known as the extrinsic innervations of

the brain circulation. Specific perivascular structures of an intrinsic origin come into view after arterioles leave the Virchow–Robin space to penetrate the cerebral cortex, the latter including subcortical innervations. Spontaneous vasomotions originate from active mechanisms existing in cortical vessels, which to some extent are influenced by these innervations. However, the perfusion of the brain rapidly increases in areas where the activity of neuronal networks is prolonged or enhanced. In such a case, the CBF is locally intensified, a phenomenon denominated functional hyperemia. It is hypothesized that such a blood flow increase is accomplished by increased capillary blood velocity rather than capillary recruitment. From many years now, researchers have been trying to elucidate the basic principles for this phenomenon (Riera and Sumiyoshi 2010). We summarize below six major pathways by means of which neurons could communicate with the surrounded vasculature. They can be classified into two major groups: (1) a **phasic signaling** (e.g., gases, neurotransmitters, and lipids) issued directly from the neurons may reach the microvasculature through either fuzzy diffusion or local axonal release and b) a **tonic signaling** (i.e., Ca^{2+} waves underlying long-term brain requirements such as metabolites/oxygen) originated from gap-junction-connected astrocytes, which is evoked by the release of various neurotransmitters from nearby neurons during activation.

1. The release of large vasoactive molecules [e.g., neuropeptide Y (NPY), vasointestinal polypeptide (VIP), somatostatin (SOM), cholecystokinin (CCK), and acetylcholine (ACh)] by GABAergic interneurons through direct innervations of neighboring (even distances $>100\ \mu\text{m}$ away from the cells) microvessels. Some nitrergic GABAergic interneurons with specific laminar profiles in the neocortex transmit also neuronal signals from subcortical regions to the vasculature of a given cortical area. (**phasic signaling**).
2. The release of nitric oxide into the extracellular space from the axon terminals of some GABAergic interneurons via activation of the nNOS. These interneurons could release these large vasoactive molecules perivascularly through vessel innervations. This particular population of interneurons is very small and is not homogeneously distributed along the cortical layers. As nitrergic glutamatergic neurons are very rare in the neocortex, this mechanism might be very specific for inhibitory neuronal networks. The impact of such neuronal nitric oxide signaling on the vasculature via a cyclic GMP (cGMP)-dependent mechanism has been proposed to be modulatory rather than mediatory. (**phasic signaling**).
3. The release of prostaglandin E2 (PGE2) from certain pyramidal cells, which have dendritic and axonal profiles containing inducible prostanoid-synthesizing enzyme cyclooxygenase-2 (COX-2). These specific glutamatergic neurons are frequently in close proximity to the penetrating microvessels. Released PGE2 might reach a variety of receptors on either nearby glial processes or vascular smooth muscle cells (SMCs). COX-2 is peculiarly restricted to presynaptic and postsynaptic regions in these pyramidal cells, showing robust synaptic antilocalization with the nitric oxide-synthesizing enzyme. Nitric oxide diffusion into the synaptic sites of these glutamatergic neurons may result in COX-2 activation. Cortical microvessels are also targets of axonal varicosities of such pyramidal cells. (**phasic signaling**).
4. Enhancements of astrocytic Ca^{2+} signaling cause the production of arachidonic acid through the action of phospholipase A2 enzymes on membrane phospholipids. Arachidonic acid is able to diffuse towards adjacent cells, where it serves as a substrate for two cytochrome P450 enzymes (i.e., CYP4A subtype in SMCs and CYP2C subtype in astrocytes) to produce 20-hydroxyecosatetraenoic (20-HETE) and epoxyecosatrienoic (EET) acids. 20-HETE has a contractive effect on the SMCs through the activation of the l-type calcium channels and deactivation of the calcium-activated potassium (BK) channels. EET diffuses into the tissue, producing vasodilations by

hyperpolarizing nearby SMCs through the activation of BK channels. The negative and positive effects on the activation of BK channels in the SMCs caused by 20-HETE and EET acids, respectively, may be in equilibrium with low levels of nitric oxide, which constitutes an inhibitory agent for CYP4A. This equilibrium gives way whenever nitric oxide dissemination in the tissue increases. Nitric oxide signaling from neurons and endothelial cells activates the soluble guanylate cyclase in the SMCs, resulting in cGMP-related muscle relaxations. **(tonic signaling).**

5. Arachidonic acid increase causes PGE2 production from the astrocytic constitutive COX-1 enzyme. This lipid diffuses in the tissue and via PGE2 receptors could stimulate cyclic AMP formation in SMCs. The intracellular lactate is used by the astrocytic prostaglandin transporter to take up extracellular PGE2. However, when extracellular lactate levels are increased, this PGE2 clearance mechanism is lost, causing augmented vasodilations. The extracellular lactate rises by enhancing the activity of the lactate dehydrogenase enzyme, for example, increasing the substrate levels (pyruvate and NADH) of this redox reaction. Indeed, the levels of these substrates increase under either hyperglycolytic activity or suppression of the tricarboxylic acid (TCA) cycle. Astrocytic lactate transported to the extracellular space by monocarboxylate transporters MCT-1 provides a signaling that bring together metabolism and functional hyperemia through the lactate–PGE2 coupling mechanism. **(tonic signaling).**
6. External K^+ promotes dilation of vessels through Kir2.1 channels in SMCs. Large-conductance BK channels have been found in astrocytic end feet, which might open in response to significant Ca^{2+} increases. A variant of this hypothesis, named the K^+ siphoning, was initially proposed as a mechanism for controlling the vascular tone through astrocytic Kir4.1, but recently criticized. **(tonic signaling).**

The spatiotemporal profiles of these mechanisms show strong laminar variations (Herman

et al. 2013; Hirano et al. 2011) as a function of the brain state (Maandag et al. 2007; Smith et al. 2002).

Cortical Microcircuits

Cortical neurons display a wide variation in their morphological, electrophysiological, synaptic, and molecular properties. The clearest distinction is between pyramidal cells (e.g., “principal cells,” DeFelipe and Fariñas 1992) and interneurons. Interneurons are divided into excitatory (spiny stellate cells) and inhibitory types (Markram et al. 2004).

Pyramidal neurons (PCs) comprise more than 70% of all cortical neurons. They are the main output source of the neocortical microcircuit, projecting to subcortical brain areas such as the thalamus, basal ganglia, and brainstem but also connecting cortical regions, e.g., the contra- and ipsilateral sections of a sensory area. Although they appear in a variety of forms, the following common features are typically reported: (a) an apical dendrite branch which extends from the soma vertically towards the cortical surface with a gradually tapering form and (b) basal dendrites which originate from the soma towards random transversal directions. PC dendrites have highest spine density in the middle portions of the apical dendrite. Their axons project vertically downwards into the white matter after sending local collaterals within the cortical layers. The apical dendrites of layer VI PC project also to non-vertical angles before climbing up towards the superficial layers. Some PCs generally form a dendritic tuft in layer I. Local axon collaterals of PCs innervate neighboring cortical neurons. Layer V thick-tufted PC constitutes one of the best known types of cortical neurons. Their apical dendrite always reaches layer I where it bifurcates extensively forming a wide tuft. These neurons have broad basal dendrites that span radially up to 300 μm around the soma. The local axonal collaterals of this neuron project vertically to all layers and horizontally within layers V and VI. They project to deeper brain areas (e.g., superior colliculus and brainstem nuclei). These neurons are considered the microcircuit integrators of inputs from neurons in all cortical layers, which

eventually result in the main cortical outputs. These typical cytoarchitectonic structures for principal cells in occipital and parietal – and, to a lesser extent, temporal – lobes are not conserved in prefrontal cortices.

Interneurons consist of ~20% of neocortical neurons. Interneurons lack of apical dendrites. Their axons are mostly confined to the same functional column. Usually, interneurons do not project to other cortical areas via the white matter, i.e., they are “local circuit neurons.” In terms of their dendritic spine density, interneurons are divided into smooth, sparsely spiny, and spiny cells. These neurons have a very diverse axonal ramification, with characterization established according to the postsynaptic domain (axon, soma, or dendrite) innervated by them. Spiny stellate cells are the only excitatory interneurons and they are mostly located in layer IV of primary sensory cortices. They constitute the major input to the cortex from subthalamic nuclei. They display radially projecting spiny dendrites originated from small somata, some of them spreading to neighboring layers. Inhibitory interneurons have a large diversity of morphological and electrophysiological properties, which help interneuron classification. According to their arborizations, inhibitory interneurons are subclassified into bipolar, bitufted, and multipolar neurons.

- *Basket cells (BC)* are the most common inhibitory interneurons in the neocortex. They are found in cortical layers II–VI. There are three main subclasses of BC (i.e., large, small, and net). Their dendrites extend to different directions, with the morphology being multipolar and dendrites either smooth or sparsely spined.
- *Chandelier (axo-axonic) cells* are found throughout layer II to V in different cortical areas of mammals. They have an ovoid-like soma, from which smooth (or sparsely spined) dendrites develop in opposite directions. Their dendrites can be found in cortical layers I–VI, and their axons form a candle-like arrangement of vertical bouton strings that target PC axon initial segments, primarily in the supragranular layer. This type of neurons plays a crucial role in controlling PC activity.
- *Double bouquet cells (DBC)* are interneurons present in superficial layers with vertically oriented ovoid-like somata. Therefore, they have two dendritic bundles that extend from two opposite directions. Their axons form tight axonal bundles that descend vertically to infragranular layers. They display a regular spacing into microcolumns.
- *Martinotti cells* are interneurons with bitufted dendritic morphology and an ovoid soma. They are primarily found in cortical layers II–VI. Their axons ascend to and spread in layer I up to a few millimeters laterally from the somatic location. They inhibit the tuft and distal dendrites of PCs.
- *Neurogliaform cells* are small interneurons existing in all cortical layers. They have fine and multipolar-spanning dendrites. Their axons are thin and extensively branched. They innervate PCs with GABA type B synapses.

Main Microcircuit Principles

Cortical neurons display a large variety of geometrical and intrinsic electrophysiological properties (DeFelipe et al. 2002). These properties determine the input–output relationships for each particular neuron. They depend on the expression of ionic channels along the dendrites as well as on the geometry of dendritic trees. Cortical neurons are engaged in different time scales. The single-cell mRT-PCR method allows the establishment of relationships between ion-channel expression patterns and electrophysiological profiles of cortical neurons. A widely used classification scheme considers neurons as (a) regular spiking (RS), (b) fast spiking (FS), and (c) intrinsic bursting (IB), which rely only on the response to long suprathreshold stimuli. With the addition of the “chattering cell” type, this classification scheme has been used to quantitatively evaluate electrophysiological behaviors in vivo. Two other electrophysiological types of neurons have been later added to the original scheme: (a) low-threshold spiking (LTS) and (b) late spiking (LS). The majority of synaptic connections in the neocortex are between PCs, most of them in layer V (formed on basal, apical, oblique, and tuft dendrites).

Short-term connections between spiny stellate neurons in layer IV are formed on dendrites. Interlaminar connections between excitatory neurons target also dendrites. The spatial properties of excitatory and inhibitory synaptic inputs determine the efficacy at which individual neurons are excited. Synapses are distributed at specific distances from the soma (i.e., Euclidean and electrotonic distances) and with targeted locations relative to dendritic bifurcations and branches. Ionic channel densities along dendritic trees, soma, and axon, as well as their reversal potential distributions, play an important role in the genesis/propagation of action potentials. For example, as a consequence of the higher values of chloride reversal potential at the postsynaptic location (axon initial segment), chandelier cells have excitatory effects on PCs. Due to the physical proximity, axon- and soma-targeting synapses can immediately affect the action-potential initiation; hence, they act as action-potential “editors.” Distal dendritic synapses have low temporal precision because signals produced by them are filtered at the soma and initiation zone. Dendritic spines are the preferable postsynaptic targets of most excitatory synaptic connections. They play a crucial role in dendritic integration and synaptic plasticity. Although dendritic arbors are physically stable, dendritic spines and filopodia are variable elements (i.e., elimination and growth). These spines are the means by which dynamically postsynaptic target cells connect selectively to specific presynaptic boutons. The selectivity of synaptic contacts between cortical neurons can be divided into two separate questions: (i) selectivity in the postsynaptic element being connected to and (ii) selectivity in the unique identity of the innervated neuron.

(i) *Domain selectivity*

- (a). Axon-targeting cells (e.g., chandelier cells).
- (b). Somatic and perisomatic targeting interneurons (e.g., basket cells).
- (c). Dendritic targeting cells (e.g., double bouquet, neurogliaform, and Martinotti cells).

(ii) *Target cell selectivity*

How does a neuron choose its postsynaptic partners? The selection of a target pyramidal neuron by chandelier cells may occur because of a random axodendritic proximity with a further proliferation as the result of local interactions. While both basket and chandelier cells develop connections to neighboring cells, they selectively decided which PCs are going to be their final target, for which multiple boutons will be created around the axon initial segment. This selection process cannot be explained by random processes and geometrical considerations, which is far from the characteristic connectivity patterns between pyramidal neurons.
